To my wife, Kimberly, your loving support and encouragement created the environment to write this book, and your patience allowed me to focus on this book away from what I enjoy most—being with you.

To my son, Colin, your computer expertise has been immensely helpful solving the technical issues in this book, and I admire the application of those skills to the development of your own company, Bookrenter.com.

To my daughter, Shannon, sharing your knowledge for the treatment of animals and your passion for becoming a veterinarian is a great joy for me.

PART 1 FOODBORNE and MICROBIAL TOXINS 1

I Chemical Contamination and Additives 5
by Cyrus Rangan, MD, FAAP

1 Food Contamination 5

2 Food Additives and Sensitivities 22

II Staples and Spices 34

3 Akee Fruit and Jamaican Vomiting Sickness (*Blighia sapida* Köenig) 34

4 Cinnamon (*Cinnamomum* Species) 39

5 Cyanogenic Foods (Cassava, Fruit Kernels, and Cycad Seeds) 44

6 Cycad Seeds and Chronic Neurologic Disease (*Cycas* Species) 54

7 Djenkol Bean [*Archidendron jiringa* (Jack) I. C. Nielsen] 59

8 Grass Pea and Neurolathyrism (*Lathyrus sativus* L.) 62

9 Nutmeg (*Myristica fragrans* Houtt.) 67

10 Pepper and Capsaicin (*Capsicum* and *Piper* Species) 71

11 Potatoes, Tomatoes, and Solanine Toxicity (*Solanum tuberosum* L., *Solanum lycopersicum* L.) 77

12 Rhubarb and Oxalosis (*Rheum* Species) 84

III Microbes **89**

A Bacteria **89**
by Cyrus Rangan, MD, FAAP

13 *Bacillus cereus* 89

14 *Campylobacter jejuni* 96

15 *Clostridium botulinum* (Botulism) 103

16 *Clostridium perfringens* 114

17 *Escherichia coli* 120

18 *Listeria monocytogenes* 133

19 *Salmonella* 141

20 *Shigella* Species (Shiga Enterotoxins) 150

21 *Staphylococcus aureus* 156

22 *Streptococcus* Species 162

23 *Vibrio* Species 167

24 *Yersinia enterocolitica* 174

B Other Microbes **181**

25 Cyanobacteria 181

26 Protozoa and Intestinal Parasites 191

27 Gastrointestinal Viruses 202

IV Seafood **212**

28 Amnesic Shellfish Poisoning and Domoic Acid 212

29 Azaspiracid Shellfish Poisoning and Azaspiracid Toxins 218

30 Diarrhetic Shellfish Poisoning and Okadaic Acid 222

31 Neurotoxic Shellfish Poisoning and Brevetoxins 227

32 Paralytic Shellfish Poisoning and Saxitoxins 231

33 Ciguatera Fish Poisoning and Ciguatoxins 238

34 Puffer Fish Poisoning and Tetrodotoxin 247

35 Red Whelk and Tetramine 253

36 Scombroid Fish, Scombrotoxin, and Histamine 256

PART 2 FUNGAL TOXINS **261**

I Mushrooms **265**

37 Amatoxin-Containing Mushrooms 265

38 False Morel and Gyromitrin Poisoning 285

39 Gastroenteritis-Producing Mushrooms 290

40 Inky Cap and Coprine Toxicity [*Coprinus atramentarius* (Bull.) Fr.] 294

41 Isoxazole-Containing Mushrooms and Pantherina Syndrome (*Amanita muscaria, Amanita pantherina*) 298

42 Muscarine-Containing Mushrooms and Muscarine Toxicity (*Clitocybe* and *Inocybe* Species) 303

43 Orellanine-Containing Mushrooms and Nephrotoxicity (*Cortinarius* Species) 307

44 Paxillus and Other Mushroom Syndromes 312

II Mycotoxins 317

45 Mycotoxins 317

PART 3 MEDICINAL HERBS and ESSENTIAL OILS 373

I Medicinal Herbs 377

46 Aloe Vera [*Aloe vera* (L.) Burm. f.] 377

47 Aristolochic Acid and Chinese Herb Nephropathy 382

48 Black Cohosh (*Actaea racemosa* L.) 388

49 Blue Cohosh [*Caulophyllum thalictroides* (L.) Michx.] 394

50 Borage (*Borago officinalis* L.) 397

51 Burdock Root (*Arctium lappa* L.) 400

52 Calamus (*Acorus calamus* L.) 403

53 Camphor (*Cinnamomum camphora* T. Nees & Eberm.) 407

54 Cascara (*Frangula purshiana* Cooper) 414

55 Cat's Claw [*Uncaria tomentosa* (Willd. ex Schult.) DC.] 421

56 Chamomile [*Chamomilla recutita* (L.) Rauschert, *Chamaemelum nobile* L.] 425

57 Chaparral [*Larrea tridentata* (Sesse & Moc. ex DC.) Vail] 429

58 Chaste Tree (*Vitex agnus-castus* L.) 434

59 Clove and Eugenol [*Syzygium aromaticum* (L.) Merr. & L. M. Perry] 437

60 Colocynth [*Citrullus colocynthis* (L.) Schrad.] 443

61 Coltsfoot (*Tussilago farfara* L.) 446

62 Comfrey and Other Pyrrolizidine-Containing Plants 449

63 Cranberry (*Vaccinium macrocarpon* Aiton) 458

64 Dong Quai [*Angelica sinensis* (Oliv.) Diels] 461

65 Feverfew (*Tanacetum parthenium* Schultz Bip.) 465

66 Garlic (*Allium sativum* L.) 470
67 Germander (*Teucrium chamaedrys* L.) 477
68 Ginger (*Zingiber officinale* Roscoe) 482
69 Ginkgo Tree (*Ginkgo biloba* L.) 488
70 Ginseng 497
71 Goldenseal (*Hydrastis canadensis* L.) 504
72 Hawthorn (*Crataegus* Species) 510
73 Impila, Pine Thistle, and Atractyloside 514
74 Jin Bu Huan and Tetrahydropalmatine 518
75 Juniper (*Juniper communis* L.) 522
76 Kava (*Piper methysticum* Forster) 525
77 Lavender (*Lavandula* Species) 532
78 Licorice (*Glycyrrhiza* Species) 537
79 Ma Huang (*Ephedra* Alkaloids) 545
80 Milk Thistle [*Silybum marianum* (L.) Gaertner] 553
81 Passionflower (*Passiflora incarnata* L.) 558
82 Pennyroyal and Pulegone (*Mentha pulegium* L.) 563
83 Purple Coneflower and Other *Echinacea* Species 568
84 Rosemary (*Rosmarinus officinalis* L.) 574
85 Rue (*Ruta graveolens* L.) 579
86 Sassafras [*Sassafras albidum* (Nutt.) Nees] 582
87 Saw Palmetto [*Serenoa repens* (Bartram) J.K. Small] 586
88 Senna (*Senna alexandrina* P. Mill.) 591
89 Skullcap (*Scutellaria lateriflora* L.) 596
90 St. John's Wort (*Hypericum perforatum* L.) 600
91 Star Anise (*Illicium verum* Hook. F. and *Illicium anisatum* L.) 607
92 Star Fruit (*Averrhoa carambola* L.) 611
93 Tansy (*Tanacetum vulgare* L.) 614
94 Valerian (*Valeriana officinalis* L.) 617
95 Yarrow (*Achillea millefolium* L.) 623
96 Yohimbe Bark and Yohimbine (*Pausinystalia yohimbe* Pierre ex Beille) 627

II Essential Oils 632

97 Citronella Oil [*Cymbopogon nardus* (L.) Rendle] 632
98 Citrus Oil and Limonene 635
99 Eucalyptus Oil (*Eucalyptus* Species) 644

100 Neem Oil (Margosa Oil) (*Azadirachta indica* Adr. Juss.) 648
101 Peppermint Oil (*Mentha* x *piperita* L.) 653
102 Tea Tree Oil (*Melaleuca* Species) 658
103 Tung Oil (*Aleurites fordii* Hemsl.) 663
104 Turpentine and Pine Oil (*Pinus* Species) 666

PART 4 TOXIC PLANTS 673

I Plant Dermatitis 677
105 Plant Dermatitis 677

II Bulbs, Rhizomes, and Tubers 690
106 Buttercup Family 690
107 Colchicine-Containing Plants 693
108 Daffodils and Other Emetic Bulbs 703
109 Death Camas 707
110 Kaffir Lily [*Clivia miniata* (Lindley) Bosse] 710
111 Snowdrop (*Galanthus nivalis* L.) 712
112 Zephyr Lily (*Zephyranthes* Species) 716

III Beans 718
113 Castor Bean and Ricin (*Ricinus communis* L.) 718
114 Cowitch and Horse Eye Bean (*Mucuna* Species) 727
115 Jequirity Bean and Abrin (*Abrus precatorius* L.) 729
116 Mescal Bean [*Sophora secundiflora* (Ortega) Lagasca ex DC.] 733

IV Nonwoody Plants (Herbs) 736
117 Aconite Poisoning and Monkshood 736
118 African Blue Lily (*Agapanthus* Species) 743
119 Red Baneberry [*Actaea rubra* (Aiton) Willd.] 745
120 Begonias 747
121 Yellow Bird-of-Paradise [*Caesalpinia gilliesii* (Hook.) Wallich ex D. Dietr.] 749
122 Century Plant (*Agave americana* L.) 751
123 Cleistanthin, Diterpene Esters, and the Spurge Family (Euphorbiaceae) 754
124 Cyanogenic Plants and Laetrile® 760
125 Dieffenbachia and Other Oxalate-Containing House Plants 768

126 Digitalis-Containing Flowers (Foxglove, Lily of the Valley) 773
127 Jimson Weed and Other Belladonna Alkaloids 776
128 Lupines and False Lupine 784
129 Mayapple (*Podophyllum peltatum* L.) 788
130 Mistletoe 792
131 Poison Hemlock (*Conium maculatum* L.) 796
132 Pokeweed (*Phytolacca americana* L.) 800
133 European Bittersweet and Other *Solanum* Species 803
134 Sweet Pea and Osteolathyrism 806
135 Tree Tobacco and Other Piperidine-Containing Plants 809
136 *Veratrum* Alkaloids 815
137 Wandering Jew (*Tradescantia fluminensis* Vellozo) 819
138 Water Hemlock and Water Dropwort 821
139 White Snakeroot [*Ageratina altissima* (L.) King & H.E. Robins] 826

V Shrubs and Vines 829

140 Barbados Nut (*Jatropha curcas* L.) 829
141 Boxwood (*Buxus sempervirens* L.) 832
142 Buckthorn [*Karwinskia humboldtiana* (J.A. Schultes) Zucc.] 834
143 Cactus 837
144 Carolina Jessamine [*Gelsemium sempervirens* (L.) St. Hil.] 841
145 Daphne (*Daphne mezereum* L.) 843
146 Dog Laurel (*Leucothoe* Species) 845
147 Dogbane Family and Cardenolides 847
148 Holly (*Ilex* Species) 861
149 Honeysuckle (*Lonicera* Species) 863
150 Ivy and Falcarinol 865
151 Lantana (*Lantana camara* L.) 867
152 Rhododendrons and Grayanotoxins 870
153 Snowberry [*Symphoricarpos albus* (L.) Blake)] 874
154 Squirting Cucumber [*Ecballium elaterium* (L.) A. Richard] 876
155 Wisteria 879

VI Trees 881

156 Black Locust (*Robinia pseudoacacia* L.) 881
157 Buckeye (*Aesculus* Species) 883
158 Chinaberry (*Melia azedarach* L.) 886

159 Golden Chain Tree (*Laburnum anagyroides* Medikus) 889
160 Karaka Nut (*Corynocarpus laevigatus* J.R. & G. Forst.) 892
161 Oaks (*Quercus* Species) 894
162 Pepper Tree (*Schinus* Species) 897
163 Yew (*Taxus* Species) 899

INDEX 1135

FOREWORD

Men and women live in a miraculous world, surrounded by natural beauty, diverse environmental conditions and habitats, and evolutionary marvels. Within this intricate assembly of flora and fauna, many plant and animals have evolved that are more than passive inhabitants of this planet. They are endowed with substances both offensive and defensive, namely, potent toxins capable of slowly poisoning or rapidly subduing very large animals, including humans. In addition, modern man utilizes plant and animal products and extracts for commercial, medical, religious, and other purposes. These exposures range from naturopathic cures to a casual encounters with cactus spines during a wilderness expedition, from a diver's encounters with the needles of sea urchins to covert politically motivated assassinations utilizing ricin from castor beans. Wild mushroom foragers grow old only if they are not too bold, while amateur aquarists who reach into their saltwater tanks learn about the toxicity under the cover of lionfish plumage.

We can never learn or know too much about how best to deal with natural toxins, whether we seek to eliminate them from our immediate food supply or treat acutely intoxicated victims. Furthermore, from the understanding of syndromes and therapies, we are offered insights into their possible therapeutic value. No matter what the ultimate fate of man, the seeds, spores, fangs, and venom glands will survive. While the relationship of toxins to humans may not be always be characterized as symbiotic, there will remain a coexistence that is predicted, yet always in part unpredictable.

The medical toxicology of natural substances is predicated upon their existence, which will diminish as humans continue to erode and consume their environment. Until then, we should continue to catalogue, record, evaluate, and teach. Medical practitioners and toxicologists should accept the responsibility to perpetuate these traditions because the wisdom of indigenous shamans is being lost as rapidly as the rainforests in which they reside.

What we do not seek to protect may soon disappear. It is my fervent wish that this book not only serve as a superb medical reference for those who seek to cure, but that all who read it are inspired to preserve the landscapes and seascapes that support the origination of everything that is natural and sustainable upon this Earth.

Paul S. Auerbach, MD, MS, FACEP, FAWM

Division of Emergency Medicine, Department of Surgery,
Stanford University School of Medicine
Stanford, California

PREFACE

Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals is designed to provide in-depth, evidence-based coverage of the most important natural toxins. This book is the first of a four volume series in Medical Toxicology, which will include drugs of abuse and psychoactive plants, occupational and environmental exposures, and pharmaceutical overdoses. Scientific knowledge in the field of Medical Toxicology increased considerably since I co-authored the First Edition of *Medical Toxicology: Diagnosis and Treatment of Human Poisoning* with the late Matthew J. Ellenhorn, published in 1988. That book was designed as an authoritative, concise volume for the immediate treatment of poisoning including natural toxins, pharmaceutical agents, and occupational exposures. In the last 20 years, sufficient interest has developed in natural toxins, food contamination, medicinal herbs, chronic occupational exposures, and bioterrorism to justify coverage of the field of Medical Toxicology by a book series rather than a single volume. *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals* retains the consistent, formatted style I developed for the First Edition of *Medical Toxicology: Diagnosis and Treatment of Human Poisoning*. Once the reader is familiar with the templates used in my book series, the consistency of the organization allows the reader quickly to locate the appropriate information necessary for informed decisions regarding the sources, effect, regulation, recognition, and management of toxic exposures.

Conversions for length and temperature in metric and imperial systems are provided to ease the use of this book by an international readership, whereas the metric system for mass and concentrations are retained to limit any confusion about doses in the United States.

The following provides organizational details on the material under the headings for each toxin:

History provides interesting historical facts involving the use and recognized effects of the toxicity of natural substances.

Identifying Characteristics and **Botanical Descriptions** helps the reader identify the characteristics and geographic distribution of the specific toxin (e.g., venomous animal, toxic plant).

Exposure discusses the sources, uses, and regulation of exposures to these toxins.

Principal Toxins identifies the main toxins in the natural substances and provides data on the chemistry, structure, and physical properties of the toxin that are important for the reader's understanding of the clinical response to the toxin. This part discusses the basic science and the composition of the toxins along with factors that affect the delivery of the toxin including discussions of the venom apparatus and seasonal variation in the locations of the toxins. Additionally, this part covers the biochemical and pathophysiological basis for the toxic responses.

Dose Response covers data on the lethality and clinical effects of the toxin both in animals and in humans as well as factors that affect the potency of the toxin. The emphasis is on dose-related effects, but important adverse and idiosyncratic reactions are also discussed.

Toxicokinetics discusses the disposition of the principal toxins in the body including the distribution, absorption, and elimination of the principal toxins. The emphasis is on human data, but animal data may be included when human data are sparse.

Clinical Response provides data on the clinical features of poisoning following exposure to the toxin including the onset, duration, and type of clinical effects.

Diagnostic Testing covers information important to the interpretation of the clinical significance of the laboratory data. This section includes current laboratory methods to determine the presence of the toxin, effects of storage, biomarkers of exposure in blood, urine, and postmortem material, and the laboratory abnormalities detected by imaging studies and ancillary tests.

Treatment provides details on current methods to treat the poisoning including information important for first responders, life-threatening problems associated with the poisoning, the use of antidotes, and measures of supportive care.

Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals focuses on scientifically validated facts about specific toxins based on clinical experience and the medical literature. References are documented to validate the statements and to provide sources for further inquiry. The interdisciplinary, evidence-based approach is designed to reach beyond clinical settings to increase the scientific understanding of those in associated fields (analytical laboratories, universities, regulatory agencies, coroner's offices) involved with decisions regarding toxic exposures. My hope is that increased scientific communication between the fields aligned with Medical Toxicology will inspire more inquiry into the pathophysiology, clinical effects, biomarkers, treatment, and prevention of toxic exposures.

Donald G. Barceloux, MD

June 12, 2008

ACKNOWLEDGMENTS

I deeply respect the expertise and appreciate the dedication of the following people for their help in improving the quality, depth, and accuracy of my book, *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals*.

Bob Esposito, Senior Editor, John Wiley & Sons
His belief in the importance of my Book Series to the medical literature and his guidance made this book a reality.

Kate McKay, Text Editor
Her outstanding editorial comments, meticulous style, and judgment substantially improved the consistency and clarity of the text.

Ed Wickland
His support and astute advice on the medical publishing field was an essential part of the placement of this book series.

Donna Seger, MD, Managing Editor
Her management skills and resources for the arduous task of developing this book were an invaluable contribution.

Rob Palmer, PhD, Illustration Editor and Analytical Toxicology Reviewer
His breadth of analytical knowledge, clinical judgment, and artistic expertise were important contributions to the interdisciplinary approach of this book.

Cyrus Rangan, MD
His scholarly chapters on food contamination, food additives, and bacteria were vital contributions to the content of this book.

Rune Midtgaard
The sharing of his exquisite photographs from the professional gallery at Nature's Window (www.natureswindow.dk) was extremely generous.

Review Panel
The critical reviews and clinical insights of the Review Panel were an essential part of the scientific basis of this book.

CEP America
The support and shared clinical experiences of my medical colleagues have been indispensable to the completion of my book: Wes Curry, President; James Kim, Medical Director; Ken Moore, former Medical Director; Ken Nakamoto, Vice President of Medical Affairs; Phil Piccinni, Regional Medical Director; Emergency Department physicians, Mark Boettger, Ivan Schatz, Richard Dorosh, Greg Burke, Greg Murphy, Howard Friedman, Marc Eckstein, Matt Janssen, Geoffrey Pableo, John Lee, Tom Umemoto, Ali Jamehdor, Ludwig Cibelli, Brian Rhee, Vicki Shook, Hanne Rechtschaffen, Susan Salazar, Tom Edholm; and physician assistants, Anne Castle, Glenn deGuzman, Jaison Fraizer, Erin Merchant, Janet Nakamura, Frank Pastor, and Erik Smith.

Pomona Valley Hospital Medical Center
I admire the incredible hard work and dedication of the Emergency Department nurses and support staff in the care of a community challenged by difficult medical and social problems.

UCLA Emergency Department Colleagues
I appreciate all those who shared their expertise and clinical experience at UCLA Toxicology Rounds especially Marshall T. Morgan, Director of the Emergency Medicine Center and David A. Talan, Chairman, Department of Emergency Medicine, Olive View-UCLA Medical Center.

UCLA/Pomona Librarians
The writing of this book required the review of thousands of references and the technical assistance of the UCLA Biomedical and Pomona Valley Hospital Medical Center libraries, particularly Glenn Sato, Joseph Babi, and Debra Klein.

REVIEW PANEL

Joseph M. Betz, PhD
Director, Analytical Methods and Reference Materials Program, Office of Dietary Supplements, National Institutes of Health, Bethesda, MD

Jude T. McNally, RPh, DABAT
Managing Director, Arizona Poison & Drug Information Center, College of Pharmacy, University of Arizona, Tucson, AZ

Robert B. Palmer, PhD, DABAT
Toxicology Associates, Prof LLC, Assistant Clinical Professor, Department of Surgery, University of Colorado School of Medicine, Faculty Attending Toxicologist, Rocky Mountain Poison and Drug Center, Denver, CO

Sylvie Rapior, PhD
Professor of Botany and Mycology, University of Montpellier, Montpellier, France

Donna L. Seger, MD, FAACT, FACEP
Associate Professor of Medicine and Emergency Medicine, Vanderbilt University Medical Center, Medical Director, Tennessee Poison Center, Nashville, TN

Daniel L. Sudakin, MD, MPH, FACMT, FACOEM
Associate Professor, Department of Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR

Richard S. Vetter
Research Associate, Department of Entomology, University of California, Riverside, Riverside, CA

Gary S Wasserman, DO, FAAP, FAACT, FACMT
Chief of the Section of Medical Toxicology, Children's Mercy Hospitals & Clinics, Professor of Pediatrics, University of Missouri-Kansas City School of Medicine, Assistant Medical Director of the University of Kansas Hospital Poison Control Center, Kansas City, MO

Aruna Weerasooriya, PhD, FLS
Taxonomist and Manager, Medicinal Plants Garden, The University of Mississippi, University, MS

Suzanne R. White, MD, FACMT
Medical Director, Children's Hospital of Michigan Regional Poison Control Center, Dayanandan Professor and Chair, Emergency Medicine, Wayne State University School of Medicine, Detroit, MI

Saralyn R. Williams, M.D., FACEP, FACMT
Associate Professor of Medicine and Emergency Medicine, Vanderbilt University, Nashville, TN

I Chemical Contamination and Additives

Chapter 1

FOOD CONTAMINATION

Cyrus Rangan, MD, FAAP

Records of outbreaks of human illness caused by toxic contaminants in foods appeared at least several centuries BC, when mad honey poisoning was associated with an illness among troops under the command of the Greek historian and mercenary, Xenophon.[1] One of the first recorded foodborne outbreaks of ergotism occurred in Limoges, France during the Capetian Dynasty in 994 AD.[2] The ingestion of rye bread contaminated with ergot alkaloids during this epidemic caused the deaths of approximately 20,000–50,000 victims. Numerous episodes of ergotism have occurred throughout history. Although ergotism is a possible explanation for the bizarre behavior that occurred before and during the Salem Witch Trials of 1692, there is no definite evidence that ergotism was a contributing factor.[3] In the 1950s, mining operations in the Toyama region of Japan released cadmium into the Jinzu River. The use of this water for drinking and for irrigation of nearby rice fields resulted in a disease called *itai-itai* (translation: "ouch-ouch"), manifest by osteoporosis and renal dysfunction primarily in middle-aged women.[4] In the same decade, numerous neonates born near Minamata Bay, Japan, developed birth defects and neurological abnormalities after pregnant women were exposed to seafood contaminated by methyl mercury released into the bay from a local factory. A methyl mercury-based fungicide caused an outbreak of mercury poisoning in Iraq in 1971 after grain seeds treated with the fungicide were inadvertently used for food manufacturing instead of planting.[5] Prominent outbreaks of illnesses associated with chemical contamination of cooking oils include tri-*ortho*-cresyl phosphate-induced neuropathy (Morocco, 1959),[6] yusho ("rice oil disease," Japan, 1968), yu-cheng ("oil disease," Taiwan, 1979), toxic oil syndrome (Spain, 1981), and epidemic dropsy (India, 1998). Some contaminants are unavoidable in food manufacturing. In the United States, the Food and Drug Administration (FDA) imposes "Current Good Manufacturing Practices" (CGMP) on food manufacturers. These mandatory codes enable the FDA to cite food products as *unfit* if an unavoidable contaminant poses a risk of harm by violating a standard or action level for that unavoidable contaminant (e.g., aflatoxin). Food products are considered *adulterated* when concentrations of avoidable contaminants (e.g., pesticides) exceed established standards, sometimes prompting food recalls after sale and distribution.

Metal contaminants such as lead, mercury, arsenic, and cadmium come from factory emissions, mining operations, and metal-containing industrial products used in food production. Methyl mercury found in commercially sold seafood is deemed an unavoidable contaminant because contamination preexists in the raw material; therefore, the contamination does not result from food processing or distribution. Fish and shellfish acquire methyl mercury primarily from microorganisms that methylate environmental inorganic mercury compounds released primarily from industrial sources.

YUSHO and YU-CHENG

HISTORY

The first known case of yusho (rice oil disease) involved a 3-year-old girl in northern Kyushu, Japan, who had an acute onset of an acneiform rash (chloracne) in June, 1968. Her family members, followed by other familial clusters, presented to a single clinic with complaints of acneiform rash, hyperpigmentation, and eye discharge over the next 2 months. By January 1969, 325 cases were reported. After a small minority of patients initially identified rice oil as the causative agent of yusho, Kyushu University convened the *Study Group for Yusho* to investigate yusho; about 2,000 afflicted patients were subsequently identified. The clinical features of yusho included fatigue, headache, cough, abdominal pain, peripheral numbness, hepatomegaly, irregular menstrual cycles, nail deformities, and hypersecretion of sebaceous glands. A field survey of canned rice oil associated the disease with the use of "K Rice Oil" produced or shipped by the K Company on February 5–6, 1968.[7] The yu-cheng epidemic involved over 2,000 individuals in Taiwan in 1979, when an accidental leakage of thermal exchange fluid resulted in the contamination of rice-bran oil with polychlorinated biphenyls (PCBs), dibenzofurans (PCDFs), and quaterphenyls (PCQs).[8] The clinical features of yu-cheng and yusho were similar.

EXPOSURE

Source

Polychlorinated biphenyls (PCBs) and polychlorinated dibenzofurans (PCDFs) are thermal heat exchanger compounds used in food processing machinery. Leakage of these compounds into rice oils during manufacturing led to the yusho and yu-cheng outbreaks.

Yusho

Epidemiological studies revealed that 95.7% ($p < 0.01$) of surveyed patients recalled consumption of rice oil from K Company in Western Japan.[7] A case-control study revealed rice oil as the only associated etiologic factor, and a cohort study demonstrated a 64% risk of yusho in K rice oil consumers compared with no risk for nonexposed individuals.[7] Food engineers confirmed the leakage of dielectric thermal exchange fluid (Kanechlor 400) containing PCBs into the rice oil. This contaminant contained PCB compounds, primarily tetra-chlorinated biphenyls. In 1969, the Study Group initially concluded that PCBs caused yusho.[9] However, a lack of similar symptoms (besides chloracne) in PCB workers who had significantly higher tissue burdens (mean blood PCB level: 45 ppb) contradicted this conclusion. Furthermore, the dermatological lesions could not be reproduced in animals following the oral administration of PCB compounds or by Kanechlor 400, and the severity of the clinical features of yusho did not correlate to serum concentrations of PCB compounds. Therefore, other compounds (e.g., polychlorinated dibenzofurans) in the adulterated rice oil probably contributed to the development of yusho.[10,11]

Yu-cheng

As with the yusho incident, the suspected causative agents of yu-cheng were PCDFs rather than PCBs.[12] Contamination of the cooking oil occurred when PCBs used for the indirect heating of rice-bran oil leaked into the cooking oil. Repeated heating of the partially degraded PCBs produced PCDFs, as well as polychlorinated terphenyl and polychlorinated quaterphenyl compounds.[13]

Food Processing

High temperatures (>200 °C) in dielectric thermal exchange fluid during the deodorization step of oil refining contributed to the development of yusho and yu-cheng by degrading PCBs in the contaminated rice oil to PCDFs, PCDDs (polychlorinated dibenzo dioxins), and PCQs (polychlorinated quaterphenyls).[14]

DOSE RESPONSE

Exposure to toxic contaminants in the rice oil from the yusho and yu-cheng epidemics was assessed by recording the lot numbers of purchased oil containers and comparison of the volume of oil purchased to the volume of oil remaining in the containers retrieved from affected households. Consumption of the contaminated rice oil by household members was estimated by proportional distribution to each family member. Positive relationships were observed between estimated individual oil consumption and incidences of yusho and yu-cheng.[15,16] The mean concentrations of PCBs, polychlorinated quaterphenyls (PCQs), and PCDFs in five samples of contaminated cooking oil from the yu-cheng outbreak were 62 ppm, 20 ppm, and 0.14 ppm, respectively.[17] The congeners of these compounds were similar in the cooking oils from these two outbreaks, but ye-cheng cooking oil

samples contained about 10% of the concentrations of these compounds found in cooking oil from the yusho incident along with three to four times lower PCQs/PCBs and PCDFs/PCBs ratios.

A cross-sectional study of 79 patients with documented yusho demonstrated a dose-response relationship between estimated consumption of contaminated rice oil and the symptoms of extremity numbness, coughing, expectoration, and the sensation of "elevated teeth."[18] These symptoms were evaluated by self-administered questionnaires. Symptoms failing to demonstrate a dose-response relationship to the estimated ingestion of contaminated rice oil included fatigue, eye discharge, fever, headache, dizziness, abdominal pain, swollen joints, menstrual irregularities, and alopecia. The estimated mean total intake of PCBs and PCDFs by yusho patients was about 633 mg and 3.4 mg, respectively, compared with 973 mg and 3.84 mg, respectively, for yu-cheng patients.[19]

CLINICAL RESPONSE

Animal studies confirm a strong association between high concentrations of PCBs (i.e., at least 60% chlorination) in diets and the incidence of hepatic carcinomas. However, no human studies have confirmed an association between PCB exposure and cancer. Therefore, PCBs are listed as probable human carcinogens by the International Agency for Research on Cancer (IARC) and the US Environmental Protection Agency (EPA).[20]

Yusho

Clinical features of this illness included fatigue, headache, cough, abdominal pain, peripheral numbness, hepatomegaly, irregular menstrual cycles, nail deformities, and sebaceous gland hypersecretion. The most common symptoms were eye discharge, hyperpigmentation (skin, mucous membranes, nails), acneform lesions, and weakness.[19] Although the severity of these symptoms has decreased since the epidemic, follow-up studies of yusho survivors indicated that these symptoms persisted at least through 1993.[21] The chloracne resolved relatively rapidly in children, but hyperpigmentation and hypertrichosis remained in some patients. Thirteen children born to yusho-affected mothers exhibited gray-brown skin discoloration at birth ("black babies," "cola-colored babies"), but the discoloration spontaneously disappeared after several weeks. These babies exhibited no other symptoms consistent with yusho.[22]

Yu-cheng

The clinical features of yu-cheng and yusho are similar. Clinical findings include chloracne, hyperpigmentation, edema, weakness, vomiting, diarrhea, and hepatomegaly. The acneform eruptions were open comedones, papules, and pustules with dark heads distributed on the axilla, extremities, and external genitalia.[23] Abnormalities in children of yu-cheng patients included low birth weights,[24] prematurity, neurobehavioral changes such as delayed autonomic maturity,[25] normal menarche with shortened menstrual cycles,[26] abnormal reflexes, dysfunctions in visual recognition memory,[27] and decreased intelligence scores.[28] A 24-year follow-up study of yu-cheng victims demonstrated increased mortality from chronic liver disease and cirrhosis in men, but not in women.[29] There was an increased incidence of systemic lupus erythematosus in exposed women in the later years. The mortality rates for cancers were similar between the exposed group and the background population.

DIAGNOSTIC TESTING

Analytical Methods

Gel permeation chromatography and high resolution gas chromatography/high resolution mass spectrometry detect and differentiate PCBs and PCDFs in oil samples and in human samples.[30] Methods that utilize high performance liquid chromatography/mass spectroscopy (HPLC/MS) or high performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS) reliably detect the di-oleyl-phenyl amino propanediol ester (OOPAP) and other acylated phenyl amino propanediol derivatives (PAPs) in cooking oils.[31] Methods to detect OOPAP in humans are not available.

Biomarkers

Rice oil from the yu-cheng epidemic contained approximately 3,000 ppm total PCBs. The mean blood concentration of PCBs in patients with chloracne and hyperpigmentation was in the range of approximately 5 ppb. There was a linear correlation between the severity of skin lesions and the total PCB concentrations in blood samples. Studies of human and animal subjects indicate that PCB concentrations in the range of 10–25 ppm cause similar skin abnormalities. Analysis of PCBs, PCDFs, and PCQs in contaminated rice-oil samples collected from factory cafeterias, school cafeterias, and the families of patients with yu-cheng ranged from 53–99 ppm, 0.18–0.40 ppm, and 25–53 ppm, respectively.[32]

Although the specific compound associated with yusho or yu-cheng remains unknown, PCDDs are more appropriate biological biomarkers for the severity of yusho and yu-cheng than other polychlorinated hydrocarbons because the presence of PCDDs in blood samples indicates exposure to these compounds or parent compounds as PCDDs do not occur in nature.[33] These compounds persist in the blood for years.[34] Clearance of PCDFs and PCBs in humans is nonlinear with faster elimination rates at higher concentrations. In blood samples from 3 yu-cheng patients, the whole blood elimination half-life of two persistent toxic congeners, 2,3,4,7,8-pentachlorodibenzofuran (PnCDF) and 1,2,3,4,7,8-hexachlorodibenzofuran (HxCDF) was approximately $2\frac{1}{2}$ years.[35] The calculated blood elimination half-lives of the same PCDF congeners in yusho patients were more variable with median values near 10 years. In a follow-up study of 359 patients with yusho, the serum concentrations of PnCDF and PCBs remained significantly elevated over 35 years after the incident.[36] The mean blood concentration of PnCDF in exposed patients was 177.50 pg/g lipids compared with 15.2 ± 8.9 pg/g lipids in the blood of healthy controls. The blood PnCDF concentration in these patients correlated to some clinical symptoms of yusho including acneform eruption, comedones, oral pigmentation, constipation, numbness in the extremities, and body weight loss. Follow-up studies indicate that the blood elimination half-lives are shorter (i.e., about 1–5 years) for PCB congeners than PCDF congeners. Follow-up studies of blood samples from yusho patients 34 years after the incident indicate that PCDFs contribute about 65% of the remaining total toxic equivalents of dioxins (non-*ortho* PCBs, mono-*ortho*-PCBs, PCDDs, PCDFs).[37] In particular, the mean concentration of some PCDF congeners were substantially higher than controls including 1,2,3,6,7,8-HxCDF (3.9 times), 1,2,3,4,7,8-HxCDF (12 times), and PnCDF (11.3 times). The blood samples from 165 yu-cheng patients collected 9–18 months after the onset of poisoning contained 10–720 ppb PCBs with a mean value of 38 ppb.[8]

Abnormalities

Yusho and yu-cheng patients occasionally had mild elevation of serum hepatic aminotransferase concentrations, but results of most laboratory studies were within normal ranges.[38] Hepatorenal function is usually normal.

TREATMENT

The treatment for yusho and yu-cheng is supportive. Dermatologic changes may persist for several months, and topical or systemic medications typically do not alter the time-course of these lesions. Yusho and yu-cheng patients require long-term follow-up for the development of liver dysfunction and malignancy.[38]

TOXIC OIL SYNDROME

HISTORY

In the early 1980s, Spanish laws banned the importation of rapeseed oil for human consumption to protect the Spanish olive oil market.[39] These laws required the denaturation of imported rapeseed oil with aniline, methylene blue, or castor oil as a means to make this imported oil unfit for human consumption. During late 1980 and early 1981, a substantial amount of aniline-denatured rapeseed oil imported from France was fraudulently diverted for human consumption through Catalonia. These oils were diluted with other edible oils, refined, and resold through a network of distributors and itinerant salesmen. Although these oils contained aniline, the toxic oil syndrome was apparently not associated with the aniline.

During the first quarter of 1981, an oil distributor based in the center of Madrid named RAELCA entered the illicit oil sales market with mixed aniline-denatured rapeseed oil. In March 1981, RAELCA purchased five lots of aniline-denatured rapeseed oil from two French food oil companies, and they shipped three lots to the ITH oil refinery in Seville.[40] The other two lots went to the Danesa Bau refinery in Madrid. Although the denatured oils were intended for industrial use, roadside vendors sold the oils as "olive oil" to residents over a 2-month period.[41] Most of the cases of toxic oil syndrome appeared in the period from May to August 1981. Figure 1.1 displays the number of cases of toxic oil syndrome diagnosed in 1981. Epidemiological studies concluded that the ITH oil refinery was the point source for the epidemic.[42]

EXPOSURE

Source

The exact causal agent in the contaminated oil involved with toxic oil syndrome remains unknown, in part, because of the many potential toxins in denatured aniline compounds associated with this illness. In a study of toxic oil syndrome-associated oils, fractionation of

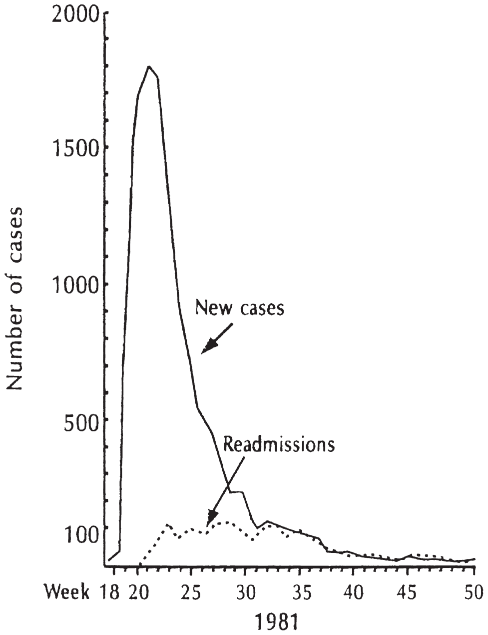

FIGURE 1.1. Onset of cases of toxic oil syndrome in Spain during 1981. From Philen RM, et al. Toxic oil syndrome and eosinophilia-myalgia syndrome: May 8–10, 1991, World Health Organization Meeting Report. Semin Arthritis Rheum 1993;23:106. Reprinted with permission from Elsevier.

the oils by high performance liquid with ultraviolet detection (HPLC/UV) and analysis by high performance liquid chromatography/atmospheric pressure chemical ionization/ tandem mass spectrometry (HPLC/APCI/MS/MS) demonstrated 115 aniline derivatives from nine aniline-related families of chemicals.[43] Toxic oil syndrome is a unique combination of vasculitis, thrombosis, and immunologic changes (e.g., T-lymphocyte activation, cytokine release) that differs from the toxicity previously associated with refinery products, additives, or contaminants.[44] The full spectrum of toxic oil syndrome has not been reproduced in experimental animals.[39] The two suspected groups of toxic compounds are fatty acid anilides and amino-propanediol derivatives (fatty acid mono- and di-esters).[45] Analysis of contaminated oil samples indicates that pentachlorophenol and pentachloroanisole were not etiological agents of toxic oil syndrome.[46]

Food Processing

In contrast to other illicit rapeseed oil distributors, RAELCA mixed the denatured rapeseed oil with other oils *after* the refining process. All other illicit refiners of denatured rapeseed oil in Catalonia mixed the denatured and edible oils *before* refining the adulterated oils. The processing of the fraudulently diverted rapeseed oil probably contributed to the formation of toxic compounds in the oil. High temperatures during deodorization catalyzed the reaction of 2% aniline with triglycerides in the rapeseed oil associated with toxic oil syndrome.[47] In experimental studies, the yield of 3-(*N*-phenylamino)-1,2-propanediol (PAP) esters in toxic oil syndrome is highest at 250–300 °C (~480–570 °F), similar to those temperatures achieved during the deodorizing step of oil refining.[48] These studies indicate that the heating of denatured oil samples stored for 3 weeks yields higher concentrations of potentially toxic PAP esters compared with samples stored for 1 week. Distillations times did not significantly affect the formation of fatty acid anilide compounds. The development of toxic oil syndrome following the ingestion of denatured rapeseed oil stored for about 1 year suggests that the toxic compounds in these contaminated cooking oils are stable for at least 1 year.[49]

DOSE RESPONSE

Dose response in toxic oil syndrome was evaluated by a case control study known as the "Toxi-Epi Study," which followed sales and distribution chains of the fraudulently distributed rapeseed oils using the chemical markers, oleyl-anilide and di-oleyl-3-phenylamino-1,2-propanediol (OOPAP). The content of these compounds varied several fold in different samples of contaminated cooking oil. Cooking oil containers with a characteristic shape purchased by residents were traced back to the ITH oil refinery in Seville in southern Spain. Analytical studies showed a linear statistical correlation between the concentration of the chemical markers detected in the refinery's oil and the log of the odds ratio for dose-response.[50] Rapeseed oil concentrations of oleyl-anilide and OOPAP traced to this plant were 1900 ppm and 150 ppm, respectively.

CLINICAL RESPONSE

The first cases of toxic oil syndrome were reported on May 1, 1981 in central and northwestern Spain. Initial epidemiological studies demonstrated clustering in incidence and mortality for toxic oil syndrome in households distributed along transportation routes throughout the affected regions. In July 1981, Spanish health officials announced that a fraudulently distributed, industrial oil sold as edible cooking oil was the etiology of this illness, initially termed pneumonic paralytic eosinophilic syndrome.[51] The Spanish government subsequently initiated a consumer exchange program for olive oil, and they stockpiled the contaminated oil for further study.[52] In 1983, the World Health Organization named the illness toxic oil syndrome.[53] The official census originally consisted of records of patients with clinically suspected toxic oil syndrome that did not necessarily fulfill the case definition of the 1981 Spanish

Clinical Commission. A 1987 review of these records by the World Health Organization Regional Office for Europe Scientific Committee for the Investigation of the Toxic Oil Syndrome indicated that about 20,000 people were affected with over 10,000 hospitalizations.[54] Although during the first few years about 300 patients died of toxic oil syndrome, the overall mortality of the cohort with toxic oil syndrome was not elevated after the first year of the epidemic when compared with the general Spanish population.[55]

Toxic oil syndrome is a progressive multisystemic disease with three distinct clinical phases (acute, intermediate, chronic). The average latency period was about 4 to 7 days after the ingestion of the contaminated oil with a maximum of about 10 days.[56] The basic underlying pathological lesion is a nonnecrotizing vasculitis with associated thrombotic events. Common initial symptoms of toxic oil syndrome included fever, cough, dyspnea, and chest pain. Other acute symptoms included urticarial rash, pruritus, abdominal cramping, and headache. The differential diagnosis for toxic oil syndrome includes other autoimmune disorders such as eosinophilia-myalgia syndrome, eosinophilic fasciitis, systemic sclerosis, scleroderma, and systemic lupus erythematosus.[57] Porphyria cutanea tarda did not occur in these patients.

Acute (Pulmonary)

The characteristic manifestation of the acute phase is the development of noncardiogenic pulmonary edema with dyspnea, alveolar-interstitial infiltrates with or without pleural effusions, peripheral eosinophilia, fever, and rash. Most patients recovered from this early pneumonic phase of the illness. Deaths during this phase occurred from respiratory insufficiency initially from degeneration of type I and type II pneumocytes and later from thromboembolic complications.[58] During the acute phase (i.e., first 2 months), the primary lesion occurs in the endothelium of multiple organs with the exception of the central nervous system.[59] Severe myalgias and muscle cramps occur at the end of the acute phase.[39]

Intermediate (Thrombotic)

About 60% of the patients with the acute phase progress to the intermediate phase that involved the development of sensory peripheral neuropathy along with intense myalgias, dermal induration, and weight loss. More serious complications during this phase began about 2 months after the onset of illness, including pulmonary hypertension and thromboembolism of large vessels. In severe cases, histological examination demonstrated proliferation of the intimal lining of the vessels along with fibrosis and thrombosis.

Chronic (Neuromuscular)

Approximately 2 months after the onset of the intermediate phase, the chronic phase of toxic oil syndrome began, characterized by sclerodermiform changes, motor neuropathy, musculoskeletal contractures, muscle wasting, myalgias, muscle cramps, weight loss, limited joint mobility, peripheral eosinophilia, hepatomegaly, pulmonary hypertension, and Sjögren syndrome.[60] Some patients developed this chronic phase without experiencing the acute pneumonic phase.[58] The most common persistent symptoms were cough and dyspnea with about 20% of affected patients developing reduction in the carbon monoxide diffusing capacity.[61] Mortality in the chronic phase was primarily due to infectious complications of respiratory insufficiency secondary to neuromuscular weakness, thromboembolism, or pulmonary hypertension with cor pulmonale.[62,63] A minority of toxic oil syndrome patients developed severe pulmonary arterial hypertension during exercise over 20 years after exposure.[64] Long-term follow-up studies of survivors suggest reduction in the quality of life of these patients with elevated rates of depression (odds ratio [OR] = 9.66), functional disabilities (OR = 4.74), and psychosocial disabilities (OR = 2.82).[65]

Mortality was high during the first year, with a significant decline in mortality rates in subsequent years.[55] Most of the decline in mortality was observed in elderly populations; however, the mortality rate in women <40 years of age increased as a result of complications from pulmonary hypertension.[66] Concurrent clustering of incidence and mortality in toxic oil syndrome suggested that a genetic predisposition determines the severity of toxic oil syndrome. Linkage mapping of the human genome revealed increased mortality in patients with a chromosome 6-associated risk factor for the HLA-DR2 phenotype.[67] Studies in enzyme mechanics implicate a role for impaired hepatic acetylation in mediating individual susceptibilities to toxic oil syndrome.[68]

DIAGNOSTIC TESTING

Analytical Methods

Analytical methods to identify and quantify OOPAP and other PAPs in contaminated cooking oil samples include high performance liquid chromatography/atmospheric pressure ionization/tandem mass spectrometry (HPLC/API/MS/MS) and HPLC/MS.[31,69]

Biomarkers

The analysis of contaminated oil was complicated by poor identification markers on cooking oil bottles during

the recall process. Two case control studies suggested a dose-related association between the presence of three fatty acid anilide compounds (oleyl, linoleyl, palmityl) and the risk of developing toxic oil syndrome.[50,70] Of these fatty acid anilide compounds, oleyl anilide occurred in the highest concentration. Subsequent analyses suggested that 3-(*N*-phenylamino)-1,2-propanediol (DEPAP), a by-product of the same reaction of aniline with triglycerides, is an equally sensitive and a more specific biomarker of toxic oil syndrome than fatty anilide compounds.[71] Animal studies suggest that the liver converts fatty acid mono- and diesters of 3-(*N*-phenylamino)propane-1,2-diol to 3-(4′-hydroxyphenylamino)-propane-1,2-diol, which generates the electrophilic metabolite quinoneimine intermediate-2 (QI-2).[72] However, the specific chemical causing toxic oil syndrome has not been identified.

Abnormalities

Laboratory changes associated with toxic oil syndrome include peripheral eosinophilia, hypertriglyceridemia, and coagulation disorders in patients with liver involvement. Analytical studies of toxic oil syndrome patients demonstrate eosinophilia and a high concentration of mRNA for T-helper-2 cytokines, IL-4 and IL-5, in the lungs.[73] Antemortem sera from fatal cases of toxic oil syndrome also contained elevated serum IL-2R and total IgE concentrations along with a high frequency of HLA-DR2 on chromosome 6.[74] The sinus and atrioventricular nodes may exhibit dense fibrosis, hemorrhages, or cystic degeneration similar to findings in scleroderma and systemic lupus erythematosus. Coronary arteries may exhibit focal fibromuscular dysplasia and cystic myointimal degeneration with embolization. Histopathological analyses show lymphocytic inflammatory lesions of coronary arteries and the cardiac conduction system, similar to the findings in eosinophilia-myalgia syndrome. Cardiac lesions associated with eosinophilia-myalgia syndrome, however, are distinguished by cytotoxic T-cells directed against cardiac neural structures and sinus nodal myocytes, whereas toxic oil syndrome cardiac lesions are characterized by a prominence of B cells and T-helper cells.[75]

Chest x-ray demonstrates an interstitial-alveolar pattern with progression to acute respiratory distress syndrome (adult respiratory distress syndrome or ARDS) in the acute phase of toxic oil syndrome.[76] Eosinophilia is a universal finding in toxic oil syndrome patients.[77] Hypoxemia, respiratory alkalosis, and an increased alveolar-arterial oxygen gradient (A-a gradient) as determined by arterial blood gases are common in patients with severe toxic oil syndrome-induced noncardiogenic pulmonary edema during the acute phase.[78]

TREATMENT

During the acute phase, respiratory compromise from ARDS is the most serious complications of toxic oil syndrome. Patients with toxic oil syndrome are also at increased risk of cardiovascular disease that may manifest several years after exposure. Echocardiography, cholesterol screening, and weight management are effective tools for the screening and detection of cardiovascular sequelae in patients with toxic oil syndrome.[79,80] Long-term neuromuscular and articular complaints are prominent, and abnormalities are treated symptomatically.[81] Patients should be monitored for the prominent risk factors most closely associated with early mortality: female <40 years old, liver disease, pulmonary hypertension, frequent pulmonary infections, motor neuropathy, and eosinophilia.[82]

EPIDEMIC DROPSY

HISTORY

Although the first of several epidemics of epidemic dropsy was documented in 1877 in Calcutta, the most prominent epidemic dropsy epidemic occurred in Delhi, India during August, 1998.[83] The Indian Ministry of Health received over 2,552 reports of poisoning with 65 deaths from August to October 1998. The incidence of epidemic dropsy was higher in lower socioeconomic groups, probably as a result of purchasing less expensive, loosely packaged mustard oil from roadside vendors. Epidemic dropsy (argemone toxicity) is characterized by the pathological accumulation of lymph throughout the body along with gastrointestinal distress, erythrocyanosis, sarcoid-like skin lesions, myalgias, paresthesias, and painful edema of the lower extremities.

EXPOSURE

Source

Argemone oil (Katkar oil) mixed with mustard oil and ghee (clarified butter) caused epidemic dropsy outbreaks in India, South Africa, and Nepal. *Argemone mexicana* L. (Mexican prickly poppy, Satyanashi [translation: *devastating*], Papaveraceae) is an invasive weed with a yellow flower similar to the mustard flower (*Brassica nigra* (L.) W.D.J. Koch). Indian mustard oil

merchants commonly remark to public health officials that argemone seeds are inadvertently harvested with mustard seeds because they thrive in similar climates, with potentially overlapping harvests (Mustard—February/March; Argemone—April/May).[84,85] However, the canopy-like structure of the mustard plant does not permit concurrent growth of other plants in the same fields; therefore, mustard seeds are generally harvested in February, leading to the widely accepted theory that adulterations of mustard oil with argemone oil are intentional.

Argemone oil contains two toxic alkaloids: dihydrosanguinarine (CAS RN: 3606-45-9, $C_{20}H_{15}NO_4$) and much smaller amounts of sanguinarine (CAS RN: 2447-54-3, $C_{20}H_{14}NO_4$). Although the concentration of dihydrosanguinarine in argemone oil is greater than sanguinaria, the toxicity of the latter compound is greater.[86] The names originate from the bloodroot (*Sanguinaria canadensis* L.), which is the original source of this alkaloid.[87] These alkaloids are benzophenanthridine derivatives of glycosides that cause increased permeability of blood vessels, particularly in the heart, liver, eyes, gastrointestinal tract, and kidneys.[88] Figure 1.2 and Figure 1.3 demonstrate the chemical structure of dihydrosanguinarine and sanguinarine, respectively.

The exact mechanism of toxicity of epidemic dropsy is unknown. Sanguinarine and dihydrosanguinarine accumulate in the gastrointestinal tract, serum, and tissues after binding tightly to plasma proteins.[89] *Potentially* these toxic alkaloids cause damage by binding to Na^+-K^+-ATPase,[90] inactivating hepatic cytochrome P-450 enzymes,[91] depleting hepatic glutathione,[92] and disrupting carbohydrate metabolism. The latter effect inhibits active transport of glucose across intestinal villi, resulting in increased glycogenolysis and the formation of excess glucose-1-phosphate, pyruvate, and lactate.[93] These processes lead to the formation of reactive oxygen species, causing oxidation of plasma proteins and lipids.[94]

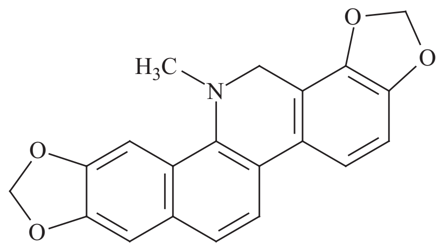

FIGURE 1.2. Chemical structure of dihydrosanguinarine.

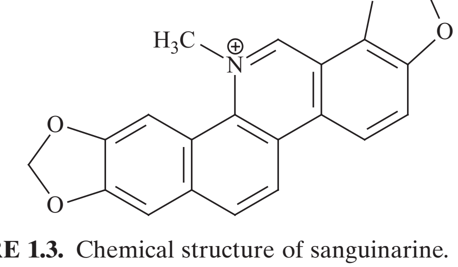

FIGURE 1.3. Chemical structure of sanguinarine.

Food Processing

Mustard seeds are differentiated from the seeds of *Argemone mexicana* L. by physical appearance: mustards seeds are smooth and round; argemone seeds are creased with spiked edges. Batches of mustard seeds are visually inspected for argemone seeds during processing with the argemone seed discarded upon detection. The practice of sorting is painstaking and cost-prohibitive, as 1% adulteration of mustard oil by argemone oil is enough to cause symptoms.[95] The early harvesting of mustard avoids the contamination of mustard oil by argemone seeds. The toxic alkaloids in argemone oil are heat-stable to 240 °C (~460 °F). Consequently, consumers in endemic areas are advised to heat mustard oils to 240 °C for at least 15 minutes to deactivate the toxic alkaloids present in argemone seeds.[96]

DOSE RESPONSE

As little as 1% adulteration of cooking oil with argemone oil is probably sufficient to cause clinical toxicity.[86] Because sanguinarine and dihydrosanguinarine accumulate in human tissue, toxicity can result from subacute, low-dose exposure.

CLINICAL RESPONSE

The clinical features of epidemic dropsy begin approximately 1–3 weeks after consumption of contaminated oil with a variety of symptoms including nausea, vomiting, diarrhea, bloating, anorexia, hyperplastic lesions in the mouth and other mucous membranes, erythematous rash with bluish mottling (erythrocyanosis), nodular sarcoid-like skin lesions or telangiectasias,[97] bilateral glaucomatous findings,[98] anemia, muscle tenderness, numbness, tingling, and painful bilateral pitting edema, particularly of the lower extremities.[99,100] Capillary leakage and congestion of gut mucosa epithelia cause watery gastrointestinal symptoms with occasional hematemesis, melena, or hematochezia. The ophthalmologic features of epidemic dropsy occur relatively late in the course of the disease. Ocular signs include increased ocular pressure and glaucoma from protein accumulation in the aqueous humor. Visual complications include subconjunctival hemorrhage, superficial

retinal hemorrhages, retinal venous dilatation and tortuosity, subhyaloid hemorrhages, macular and papillary edema, central retinal vein occlusion, visual field defects, and rarely permanent visual defects from optic nerve damage.[101–103] In a case series of 230 documented cases of epidemic dropsy, the incidence of intraocular pressures exceeding 22 mmHg was about 11% with most elevations of intraocular pressure returning to normal values within 12 weeks.[104] Inflammation of the anterior segment is usually absent.

Renal insufficiency with hypoalbuminemia and proteinuria may occur in serious cases of epidemic dropsy, resulting in acute renal failure.[100,105] Bleeding occurs from sarcoidal lesions and telangiectasias on mucous membranes and gastrointestinal epithelial mucosa.[106,107] Noncardiogenic pulmonary edema and, rarely, cardiac failure develop in severe cases with hypoxemia, respiratory alkalosis, high-output cardiac failure, tachycardia, dyspnea, and increased A-a gradient. Death results primarily from cardiac arrest secondary to congestive heart failure, noncardiogenic pulmonary edema, or pericardial fluid accumulation.[108] Postmortem histological findings include venous congestion, extramedullary hematopoiesis, focal hemorrhages, proliferation of capillary endothelial cells, dilation of hepatic sinusoids, and mononuclear infiltration of the central veins in the liver.[86]

DIAGNOSTIC TESTING

Analytical Methods

During an epidemic, samples of adulterated mustard oil are screened for sanguinarine by the addition of ferric chloride to the sample.[109] The appearance of a red-brown precipitate suggests the presence of ≥0.25% argemone oil in the sample. The presence of sanguinarine in these samples is confirmed by HPLC with limits of detection in the range of 0.001% argemone oil in the sample.[110]

Biomarkers

In a study of 45 patients with epidemic dropsy during an outbreak in New Delhi, sanguinarine was detected in eight urine samples collected within 2–3 weeks of onset of dropsy with concentrations ranging between 0.4 and 3.6 μg/100 mL. Three of 18 serum samples in the same group were positive for sanguinarine with concentrations of 1.2, 1.6, and 3.6 μg/100 mL.[111]

Abnormalities

Epidemic dropsy patients typically have hypoalbuminemia, hypocalcemia, proteinuria, and azotemia, similar to nephrotic syndrome along with reduced concentrations of tocopherol and retinol secondary to depletion of antioxidants by reactive oxygen species.[112] Chest x-ray may reveal signs of pulmonary edema and right ventricular cardiomegaly. Case series suggest that the dyspnea associated with epidemic dropsy usually results from a restrictive ventilatory defect with reduced carbon monoxide diffusing capacity rather than a cardiomyopathy.[113] The electrocardiogram may demonstrate ST-T wave changes and premature ventricular contractions.[96] Normochromic, normocytic anemia is a common finding despite expected hemoconcentration from intravascular fluid loss.[107]

TREATMENT

Treatment for epidemic dropsy is supportive. Inpatient treatment includes compression stockings, protein-rich diet, correction of symptomatic hypocalcemia, and albumin infusions as indicated by the condition of the patient. Deficiencies in tocopherol and retinol may be corrected with supplementation, but there are inadequate clinical data to determine the clinical efficacy of the administration of antioxidants to patients with epidemic dropsy.[114] Serial ophthalmologic examinations are necessary for several weeks to evaluate for the onset of glaucoma, which occurs in up to 11% of cases.[115] Topical beta-receptor antagonists (timolol, levobunolol), $alpha_2$ receptor antagonists (brimonidine, iopidine) and parasympathetics (pilocarpine) may reduce intraocular pressures. Surgical intervention with trabeculectomy or laser trabeculoplasty may be necessary in severe cases. Patients should be followed for several weeks for signs of cardiac decompensation, cardiogenic and noncardiogenic pulmonary edema, and pericardial effusion. Digitalis and diuretics may improve the outcome of cardiovascular manifestations depending on the cause of reduced cardiac output (e.g., pericardial effusion or right-sided heart failure). Full recovery generally occurs within 3 weeks to 3 months, with a 5% mortality rate.[116]

EOSINOPHILIA-MYALGIA SYNDROME

HISTORY

In 1980, Sternberg et al. reported a scleroderma-like illness with eosinophilia in a patient treated with L-5-

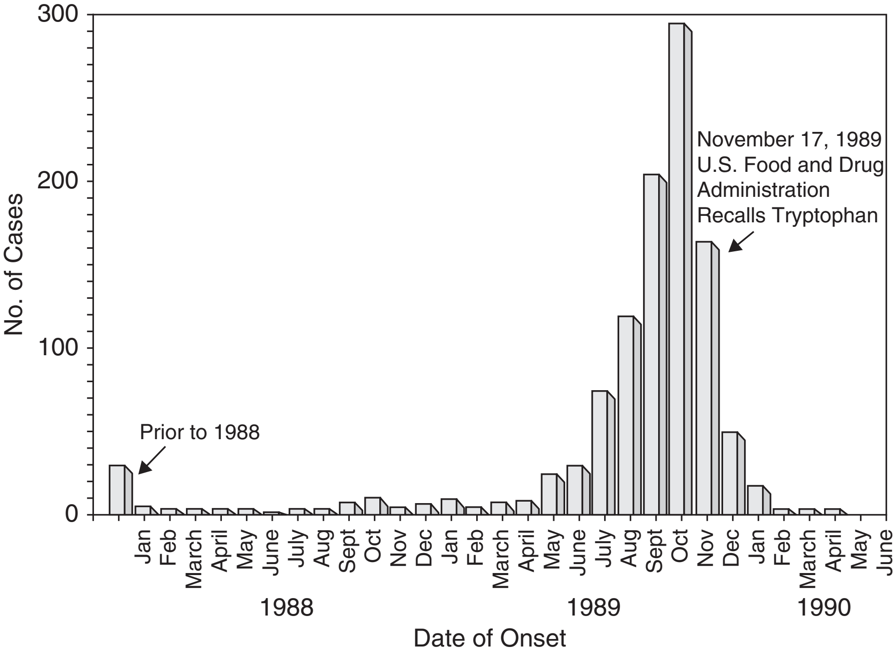

FIGURE 1.4. Onset of cases of eosinophilia-myalgia syndrome, 1988–1990. From Philen RM, et al. Toxic oil syndrome and eosinophilia-myalgia syndrome: May 8–10, 1991, World Health Organization Meeting Report. Semin Arthritis Rheum 1993;23:108. Reprinted with permission from Elsevier.

hydroxytryptophan and carbidopa.[117] In the fall of 1989, the worldwide outbreak (United States, Canada, Germany, United Kingdom) of a disease with clinical features (eosinophilia, myalgias) similar to toxic oil syndrome appeared, primarily in the United States.[118] This disease was subsequently called eosinophilia-myalgia syndrome. The first reported cases of myalgia and eosinophilia associated with L-tryptophan use occurred in three patients from New Mexico.[119] The disease subsequently affected at least 1,500 people with about 30–40 deaths. Figure 1.4 displays the onset of cases of eosinophilia-myalgia syndrome during the 1989–1990 epidemic.

Typically, patients developed intense myalgias, peripheral eosinophilia, and dermatological lesions. The onset of eosinophilia-myalgia syndrome was associated *mostly* with the ingestion of contaminated L-tryptophan manufactured by a single Japanese manufacturer (Showa Denko K.K., Tokyo, Japan).[120] Case reviews of patients who ingested L-tryptophan produced by other manufacturers (e.g., Optimax®, Merck & Co., Inc., Whitehouse Station, NJ) did not support the diagnosis of eosinophilia-myalgia syndrome in these patients.[121] Since 1991, the current surveillance system has detected a few cases of eosinophilia-myalgia syndrome. The occurrence of nontryptophan-related cases of eosinophilic-myalgia syndrome now is similar to the rate before the 1989–1990 epidemic.[122]

EXPOSURE

Source

To date, analysis of case-associated L-tryptophan from Showa Denko revealed the following six contaminants: peak AAA, (undefined); peak E, (1,1′-ethylidenebis[L-tryptophan]); peak 200, [2-(3-indolylmethyl)-L-tryptophan], peak C, (3a-hydroxy-1,2,3,3a,8,8a-hexahydropyrrolo-[2-3b]-indole-2-carboxylic acid); peak FF, [2-(2-hydroxy-indoline)-L-tryptophan]; and peak UV-5, [3-(*N*-phenylamino)-L-alanine].[123,124] The concentrations of these compounds in the L-tryptophan preparations were very low, and these concentrations did not exceed purity specification for the United States Pharmacopeia. Analysis of aniline-contaminated rapeseed oil from the toxic oil syndrome suggested a *possible* link between toxic oil syndrome and eosinophilia-myalgia syndrome, based on the structural similarity between the latter contaminant [3-(*N*-phenylamino)-L-alanine] and 3-(*N*-phenylamino)-1,2-propanediol in contaminated rapeseed oil.[125] Rodent studies indicate that metabolism of 3-(*N*-phenylamino)-1,2-propanediol

produces 3-(*N*-phenylamino)-L-alanine.[126,127] *In vitro* studies suggest that the biotransformation of 3-(*N*-phenylamino)-L-alanine by human liver microsomes produces a toxic metabolite (4-aminophenol) similar to the metabolism of the toxic biomarker (3-(*N*-phenylamino)-1,2-propanediol) associated with toxic oil syndrome.[128] Potentially, the formation of this toxic metabolite causes the release of hazardous carbonyl species. However, animal studies have not reproduced eosinophilia-myalgia syndrome following administration of implicated tryptophan lots or case-associated contaminants (peak E, peak UV-5).[129] Consequently, the identities of the responsible contaminant or contaminants remain unconfirmed. Isolated case reports have associated eosinophilia-myalgia syndrome with the ingestion of 5-hydroxytryptophan and lysine unrelated to the L-tryptophan associated with eosinophilia-myalgia syndrome.[130,131] The inability to identify specific contaminants in cases of eosinophilia-myalgia syndrome and the lack of dose-response relationships between L-tryptophan and eosinophilia-myalgia syndrome suggests that the cause of eosinophilia-myalgia syndrome is multifactorial.[132] The cause of eosinophilia-myalgia syndrome remains controversial.[133]

Food Processing

The association of eosinophilia-myalgia syndrome with the ingestion of L-tryptophan from a single Japanese company suggests that contamination of the L-tryptophan products occurred during the fermentation process with genetically modified strains of *Bacillus amyloliquefaciens*.[134] This manufacturer purified and isolated the tryptophan from the fermentation broth by using ion exchange resins followed by processing through an activated charcoal column prior to crystallization of the product. Before the epidemic of eosinophilia-myalgia syndrome, the fermentation and purification processes underwent several modifications including a reduction in the amount of activated charcoal and a change to *B. amyloliquefaciens* strain V.[135]

DOSE RESPONSE

The risk of developing eosinophilia-myalgia syndrome increased with increased consumption of L-tryptophan Showa Denko products, suggesting a dose-response effect. In a cohort of 157 individuals from a psychiatric practice using Showa Denko L-tryptophan, the number of patients developing definite eosinophilia-myalgia syndrome increased from 13% in persons using 250 mg–1500 mg/daily to 50% in persons receiving >4,000 mg/daily.[136]

CLINICAL RESPONSE

Following the index cases of eosinophilia-myalgia syndrome in New Mexico, the US Centers for Disease Control (CDC) established a voluntary national surveillance system to monitor the course of eosinophilia-myalgia syndrome. The CDC defined a case of eosinophilia-myalgia syndrome as follows: 1) peripheral eosinophil count ≥1,000 cells/mm^3, 2) generalized myalgias severe enough to disrupt the patient's usual daily activities, and 3) absence of any infection or neoplasm that accounts for the patient's symptoms.[137] Based on this relatively specific case definition, two case-control studies linked the ingestion of Showa Denko L-tryptophan with the development of eosinophilia-myalgia syndrome.[137,138] Although most authors accept the causal link between contaminated L-tryptophan and eosinophilia-myalgia syndrome, these studies have been criticized for methodological flaws including diagnostic, recall and reporting biases, bias in the inclusion and exclusion of cases and controls, inequalities between cases and controls, failure to ensure that L-tryptophan exposure preceded the illness, and failure to exclude other illness.[139,140]

The onset of eosinophilia-myalgia syndrome occurs over days to weeks, primarily in Caucasian, middle-aged women. Clinical features associated with eosinophilia-myalgia syndrome include diffuse myalgias, fatigue, headache, skin lesions (peau d'orange, fasciitis, erythematous, maculopapular rash), sicca syndrome, and sensorimotor neuropathy. These effects are similar to, but less intense than the clinical features associated with the toxic oil syndrome. For most patients, the acute phase begins with the abrupt onset of intense myalgias and peripheral blood eosinophilia along with variable degrees of weakness, edema, cough, dyspnea, paresthesias, and induration. The fingers and toes are spared, and the myalgias and weakness typically involved the proximal muscles. After a few weeks to several months, a chronic phase develops, manifest by persistent myalgias, peripheral neuropathy, cognitive dysfunction, and varying degrees of dermal sclerosis. Follow-up studies of patients with eosinophilia-myalgia syndrome suggest that the number and severity of symptoms diminishes with time.[141] Although most patients remain symptomatic, a few patients develop new symptoms one year after onset of the disease.[142] Histological features of eosinophilia-myalgia syndrome include increased collagen deposition and perivascular accumulation of eosinophils, plasma cells, and lymphocytes in affected tissue. The differential diagnosis of eosinophilia-myalgia syndrome includes relatively rare diseases, such as eosinophilic myositis, Churg–Strauss syndrome, Loeffler's syndrome, hypereosinophilic syndrome, eosinophilic gastroenteritis, and toxic oil syndrome.

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect and quantify contaminants in L-tryptophan preparations include high performance liquid chromatography (HPLC),[143] reversed phase HPLC (RP/HPLC),[144] and RP/HPLC with online ultraviolet detection and mass spectrometry.[145] The limit of detection of 1,1′-ethylidenebis(L-tryptophan) using RP/HPLC was 0.6 µg/g.

Biomarkers

Although at least six contaminants are associated with eosinophilia-myalgia syndrome, a specific contaminant responsible for eosinophilia-myalgia syndrome has not been identified. Therefore, to date there are no unique biomarkers for this disease.

Abnormalities

Case reports associated elevated serum aldolase, increased serum hepatic aminotransferases, and less frequently elevated serum creatine kinase concentrations with eosinophilia-myalgia syndrome. Antinuclear antibodies with a speckled pattern are occasionally detected. Marked peripheral eosinophilia may occur in the absence of symptoms.

TREATMENT

Treatment is supportive.

Chapter 2

FOOD ADDITIVES and SENSITIVITIES

Cyrus Rangan, MD, FAAP

HISTORY

For centuries, food additives have been used for flavoring, coloring, and extension of the useful shelf-life of food, as well as the promotion of food safety. President Theodore Roosevelt signed into law the original Food and Drugs Act in 1906.[1] This law prohibited interstate commerce in mislabeled or adulterated drugs, foods, and drinks. The Gould Amendment of 1913 required the plain and conspicuous marking of weight, numerical count, or measure on the outside of food packages. Reorganization of the US Bureau of Chemistry in 1927 resulted in the formation of the Food, Drug, and Insecticide Administration (later shortened to the Food and Drug Administration [FDA]) as a regulatory agency. The passage of the Food, Drug & Cosmetics Act of 1938 established mechanisms for providing safe tolerances for unavoidable toxic substances in food, and this act authorized standards on the identity and quality of foods. In 1940, the FDA transferred from the Department of Agriculture to the Federal Security Agency, and Walter G. Campbell became the first Commissioner of Food and Drugs.

The FDA regulates and monitors administrative, chemical, and toxicological information on food additives through a program called Priority-based Assessment of Food Additives (PAFA). This program categorizes additives in an informational database called Everything Added to Food in the United States (EAFUS) based on available toxicological information, the uses of substances in food production, and the presence of banned substances.[2] A subset of EAFUS is a list of ingredients generally recognized as safe (GRAS). Substances that are GRAS do not require FDA authorization for use as food additives.[3] Conversely, all substances introduced into the marketplace after 1958 with evidence of potential harm to humans or animals undergo FDA scrutiny and investigation. Substances prohibited from addition to food are listed in Table 2.1.

The Food Additives Amendment (1958) and the Color Additives Amendment (1960) included the Delaney clause, stating, "No additive shall be deemed to be safe if it is found to induce cancer when ingested by man or laboratory animals or if it is found, after tests which are appropriate for the evaluation of the safety of food additives, to induce cancer in man or animals." The Delaney clause authorizes the FDA to permit continued use of certain additives on a provisional basis during safety evaluations. Safety of food additives undergoes continual reexamination by the FDA. Food additives are divided into the following five broad categories according to their function: 1) taste enhancers, 2) antioxidants, 3) preservatives, 4) stabilizers & emulsifiers, and 5) coloring agents. There are over 3,000 additives approved for use in US food, including about 1,800 taste enhancers.

EXPOSURE

Environment

Natural additives derived from plant and mineral sources include caramel color, fruit juice, chlorophyll,

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

TABLE 2.1. Banned Food Additives

Banned Additive (Year)	Purpose	Source/Description	Toxicity
Calamus (1968)	Taste enhancer	β-Asarone contained in oil extract of *Acorus calamus*	Carcinogenic
Chlorofluorocarbon propellants (1978)	Preservative	Aliphatic halogenated hydrocarbons	Hepatotoxic, Cardiotoxic
Cinnamyl anthranilate (1985)	Taste enhancer	Ester of cinnamyl alcohol and anthranilic acid ($C_{16}H_{15}NO_2$)	Carcinogenic
Cobaltous salts (1966)	Stabilizer	Inorganic salts ($CoCl_2$, $CoSO_4$)	Cardiotoxic
Coumarin (1954)	Unavoidable ingredient of tonka beans	1,2-benzopyrone ($C_9H_6O_2$)	Hepatotoxic
Cyclamate (1969)	Taste enhancer	Salts of cyclohexane sulfamic acid ($C_6H_{12}NO_3S$)	Carcinogenic
Diethylpyrocarbonate (1972)	Stabilizer	Pyrocarbonic acid diethyl ester ($C_6H_{10}O_5$)	Carcinogenic
Dulcin (1950)	Taste enhancer	4-ethoxyphenylurea ($C_9H_{12}N_2O_2$)	Carcinogenic
Monochloroacetic acid (1941)	Preservative	Chloroacetic acid ($C_2H_3ClO_2$)	Carcinogenic, Neurotoxic, Cardiotoxic
Nordihydroguaiaretic acid (1968)	Antioxidant	4,4′-(2,3-dimethyltetramethylene) dipyrocatechol ($C_{18}H_{22}O_4$)	Hepatotoxic
P-4000 (1950)	Taste enhancer	5-nitro-2-propoxyaniline ($C_9H_{12}N_2O_3$)	Carcinogenic
Safrole (1960)	Taste enhancer	4-allyl-1,2-methylenedioxy-benzene ($C_{10}H_{10}O_2$)	Carcinogenic
Thiourea (1977)	Preservative	Thiocarbamide (CH_4N_2S)	Carcinogenic

annatto extracts B-G (*cis*-bixin in seeds of the tropical lipstick tree, *Bixa orellana* L.), turmeric yellow or curcumin (solvent extract of ground rhizomes of *Curcuma longa* L.), quillaia extracts (glycosides of quillaic acid from aqueous extracts of milled inner bark of *Quillaia saponaria* Molina), dried algae meal, beet juice, and paprika.[4] More recently introduced natural substances include LE399 α-amylase from *Bacillus licheniformis* (Weigmann) Chester and laccase from *Myceliophthora thermophila* (Apinis) Oorschot. The former genetically modified enzyme is used in the production of nutritive sweeteners in syrups and alcoholic beverages, whereas the latter enzyme is used for the oxidation of off-flavor phenolic compounds (e.g., *trans*-2-nonenal) in the brewing of beer.[5] Xylanase is a hydrolytic enzyme from a genetically modified strain of *Thermomyces lanuginosus* Tsikl. that improves the handling and stability of dough. Most of these enzymes are destroyed during food processing.[5] Almost all synthetic food additives are derivatives of sulfonated aromatic amines, organic acids and salts, or inorganic acids and salts.

Animal

Gelatin, a common additive, is derived from the hooves of livestock.[6] Carminic acid is a red dye extracted from the dried bodies of pregnant female cochineal (*Dactylopius coccus* Costa), which are scale-type insects farmed on cactus plantations in Peru and the Canary Islands. The bitter Italian liquor, Campari, contains carminic acid.[7]

Food

Some food additives (e.g., nitrates) occur naturally. Leafy vegetables represent almost 100% of the human daily intake of nitrates. The content of naturally occurring nitrates is not regulated by the FDA, but calculations on the cumulative estimated daily intake of nitrates include nitrates from natural sources.[8] Notame is a flavor enhancer that is a dipeptide methyl ester with a potency of about 30–60 times the sweetness of aspartame.[5]

DOSE RESPONSE

Human exposure to food additives is evaluated by the acceptable daily intake (ADI) and estimated daily intake (EDI). ADI is the federal standard for maximum allowable dietary exposure to a food additive. ADI is an index derived from the no-observed-adverse-effect level (NOAEL) from lifetime toxicological studies in animals.

NOAEL is divided by 100 to compute the ADI. EDI is a cumulative index derived from both the concentration of additives in various foods and the average daily intake of those foods. ADI and EDI are computed for every food additive, and food additive concentrations are adjusted to reflect the addition of new additives and foods. For FDA approval, the sum of all EDI's of a food additive from all sources must not exceed the ADI. These indices are utilized primarily for the evaluation of chronic effects, such as mutagenesis and carcinogenesis.[9,10] The ADI for monosodium glutamate (MSG) is 120 mg/kg/day. MSG may be associated with acute symptoms in sensitive individuals at lower doses. A randomized-controlled trial found a 33% occurrence of headache, numbness, tingling, and weakness following the ingestion of single doses of 2.5 g MSG.[11] The ADI for nitrates is 3.64 mg/kg/day. The vast majority (99%) of nitrate intake comes from leafy vegetables, with less than 1% from food additives. The EDI for nitrates is less than 70% of the ADI.[12] This safety window may explain the lack of association between nitrates and cases of human cancer. Idiosyncratic responses to food additives (e.g., methemoglobinemia) are nonimmunological and dose-independent.

CLINICAL RESPONSE

As much as 2% of the US population develops sensitivity or other adverse reactions to food additives.[13] In children with asthma, the incidence of these responses is as high as 10%.[14] Immune-mediated hypersensitivity reactions and idiosyncratic reactions comprise the majority of adverse responses to food additives. In general, there are no safety concerns for the use of alicyclic, alicyclic-fused, and aromatic-fused ring lactones as flavoring agents including tuberose lactone, mintlactone, dihydromintlactone, sclareolide, octahydrocoumarin, 3-propylidenephthalide, 3-butylidenephthalide, dihydrocoumarin, and 6-methylcoumarin.[5]

Taste Enhancers

Taste is comprised of the rudimentary sensations of sweet, sour, bitter, and salty, whereas flavor is the combined sensation of taste and the olfactory perception of food. Methods to enhance the taste of food include the addition of salts, spices, and sweeteners to food.

Monosodium Glutamate

The most closely studied taste enhancer is MSG, the sodium salt of glutamic acid. MSG enhances the savory flavors imparted by glutamic acid, which occurs naturally in proteinaceous foods (e.g., meats, seafood, stews, soups, sauces). Toxicity was first reported in 1968 as the "Chinese Restaurant Syndrome," which was characterized by the triad of palpitations, generalized weakness, and sensory numbness originating at the nape of the neck with radiation to the arms and back.[15] Controlled clinical trials have not confirmed this response to MSG, suggesting that MSG may cause symptoms only in select populations (e.g., asthmatic or atopic patients).[16,17] Short-term responses to MSG occurred in one double-blind trial of healthy patients ingesting 5 grams of MSG on an empty stomach, and in patients with severe asthma. Transient symptoms (MSG symptom complex) associated with MSG consumption included numbness, burning sensation, tingling, facial tightness, chest pain, headache, nausea, palpitations, drowsiness, and weakness.[11] These effects may result from MSG-induced stimulation of peripheral nerve receptors in the esophagus.[16] Although some epidemiological studies demonstrated correlations between MSG and adverse responses in severely asthmatic patients, a single-blind, placebo-controlled challenge study did not detect symptoms of wheezing or reduction in forced expiratory volume in 100 asthmatic patients ingesting 2.5 mg MSG.[18] Long-term health effects do not usually occur. MSG remains on the list of GRAS ingredients, but the US FDA requires manufacturers to list MSG and related compounds (monopotassium glutamate, monoammonium glutamate) on the food label. MSG was banned from the production of infant foods because of the occurrence of irreversible retinal lesions in neonatal rodents.[19]

Aspartame

Aspartame is a synthetic dipeptide formed by the reaction of L-aspartic acid with L-phenylalanine methyl ester. The gastrointestinal tract hydrolyzes aspartame to aspartyl phenylalanine and methanol. Further hydrolysis of aspartyl phenylalanine to aspartic acid and the essential amino acid, phenylalanine, produces a risk for patients with the homozygous gene for phenylketonuria (PKU). Healthy individuals hydroxylate phenylalanine to tyrosine after absorption by the gastrointestinal tract. Patients with PKU lack phenylalanine hydroxylase, and thus they can not hydroxylate phenylalanine, resulting in the accumulation of phenylalanine in the blood.[20] Acute hyperphenylalaninemia causes vomiting, agitation, a mousy odor to the urine, and a rash consistent with atopic dermatitis.[21] Chronic hyperphenylalaninemia produces hypertonia, hyperreflexia, craniofacial abnormalities, growth retardation, central nervous system dysfunction, mental retardation, and seizures. Chronic findings may be due to long-term disruption of glutamatergic synaptic transmission.[22] Individuals with

the heterozygous gene for PKU do not usually develop the clinical effects of PKU following exposure to aspartame.[23]

Saccharin

Saccharin (CAS RN: 81-07-2) is a synthetic product with 500 times the sweetness of sugar. Figure 2.1 displays the chemical structure of saccharin. In 1981, the National Toxicology Program (NTP) listed saccharin as a likely human carcinogen, based on laboratory studies demonstrating an increased incidence of bladder cancer in male rats. However, female rats and mice of either gender were not similarly affected. Continued marketing of saccharin was permitted with the provision that packages disclose the recognition of carcinogenicity in laboratory animals. In 1997, a report was issued by the NTP that bladder cancer incidence was explained by the tortuous anatomy of male rat ureters and the possible presence of contaminants in the original study. Furthermore, numerous studies documented the lack of association of human cancer to saccharin exposure.[24] Saccharin was subsequently delisted as a cause of human cancer.

Sodium Cyclamate

The synthetic sweetener, sodium cyclamate, was originally designated in the list of GRAS ingredients. The liver converts sodium cyclamate to cyclohexylamine, a well-documented cause of bladder cancer in both male and female rats. Although the extrapolated human dose equivalent for sodium cyclamate would be impossible to achieve, the additive was banned in 1969 because of strongly supportive evidence for carcinogenesis in animals.[25] Subsequent epidemiological data did not support an increased risk of bladder cancer in individuals using cyclamate or saccharin.[25] The International Agency for Research on Cancer lists cyclamates as compounds (Group 3) for which the evidence of carcinogenicity is inadequate in humans and inadequate or limited in experimental animals.

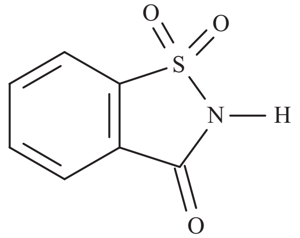

FIGURE 2.1. Chemical structure of saccharin.

Diacetyl and Bronchiolitis Obliterans

A case report of eight workers from a single microwave popcorn plant associated the developed bronchiolitis obliterans with exposure to particulates and a range of organic vapors from flavoring agents.[26] Air monitoring of this plant indicated that the predominant compounds were acetic acid and ketones (diacetyl, methyl ethyl ketone, acetoin, 2-nonanone). Additional individual case reports associated the exposure of workers at flavor-manufacturing plants with the development of bronchiolitis obliterans.[27] Subsequent cross-sectional studies confirmed the occurrence of bronchiolitis obliterans among workers from chemical production plants that produce diacetyl.[28] In this plant, the strength of association between exposure to diacetyl and severe fixed pulmonary obstruction was about 10-fold. Pulmonary abnormalities of this illness included fixed airflow obstruction, air trapping, reduced FEV_1, decreased FEV_1 to FVC ratio, and increased total lung capacity (TLC). Decline in FEV_1 exceeding 8% (>330 mL) within 6 to 12 months suggests the development of obstructive pulmonary disease.[29]

Diacetyl (CAS RN: 431-03-8, 2,3-butanedione) is a water-soluble, yellowish liquid that smells like butter and is a natural constituent of many foods. Figure 2.2 displays the chemical structure of diacetyl. This compound was the predominant ketone in air samples from this plant. The low boiling point (88 °C/190 °F) and relatively low vapor pressure (56.8 mmHg at 25 °C/77 °F) of diacetyl increase the risk of airborne exposure, but this compound has good odor and irritant warning properties. Animal studies suggest that this compound can cause airway epithelial injury, although the contribution of other compounds (e.g., acetoin, acetaldehyde) in the ambient air remains unresolved.[30] The granulocytic inflammatory infiltrates associated with diacetyl-associated bronchiolitis obliterans differs from the lymphocytic infiltrates commonly associated with posttransplant bronchiolitis obliterans.[31]

Antioxidants

Antioxidant food additives protect oily and fatty foods from spoilage by inhibiting lipid peroxidation and preventing the disintegration of lipid-soluble vitamins. Common antioxidant food additives in cereals, marga-

Butylated Hydroxyanisole **Butylated Hydroxytoluene** **Propyl Gallate**

FIGURE 2.3. Chemical structures of butylated hydroxyanisole, butylated hydroxytoluene, and propyl gallate.

rine, cooking oils and shortening, and dry mixes include ascorbic acid (vitamin C), tocopherol (vitamin E), butylated hydroxyanisole (CAS RN: 25013-16-5, BHA), butylated hydroxytoluene (CAS RN: 128-37-0, BHT), and propyl gallate (CAS RN: 121-79-9). Figure 2.3 displays the chemical structures of butylated hydroxyanisole, butylated hydroxytoluene, and propyl gallate. Antioxidants are generally nontoxic in the amounts used in food production practices.[32] Paradoxically, excessive application of antioxidants to food may promote lipid peroxidation in copper and iron-containing foods such as meats.[33] BHA and BHT are synthetic phenol-derivatives that have been associated with exacerbations of urticaria in patients with chronic urticaria.[34] High doses of BHT that far exceed the dose of BHT in food can cause human toxicity. A case report associated the onset of acute gastroenteritis (epigastric pain, vomiting, weakness, confusion, syncope) with the ingestion of 4 g BHT,[35] while the ingestion of 80 g BHT produced lightheadedness, slurred speech, unsteady gait, and lethargy. These patients recovered without sequelae.[36] Reports of carcinogenicity from BHA and BHT free-radical metabolites are limited to rodent squamous cells of the forestomach, an organ that does not have a human counterpart.[37] The International Agency for Research on Cancer (IARC) lists butylated hydroxyanisole as an animal carcinogen without evidence of carcinogenicity in humans (group 2B). Similarly, the US National Toxicology (NTP) Program lists this compound as reasonably anticipated to be a human carcinogen. Neither the IARC nor the US NTP lists butylated hydroxytoluene as a human or animal carcinogen.

At extremely high doses (i.e., 10,000 mg/kg feed), the oral administration of propyl gallate to rats causes growth retardation, anemia, hepatorenal dysplasia, and forestomach hyperplasia.[38] The ADI for propyl gallate is 0.2 mg/kg body weight as established by the US FDA. Neither the IARC nor the US NTP lists propyl gallate as a human carcinogen.

Preservatives

Preservatives enhance food safety and extend shelf-life by limiting viral, bacterial, and fungal growth. They are added to a wide variety of foods, especially those with high carbohydrate content (e.g., beverages, marmalades, jellies, jams, desserts, dairy products, breads, dough, cured meats and fish, fermented fruits and vegetables).

Benzoic Acid

Benzoic acid and sodium benzoate are most suitable for naturally acidic foods, fruit juices, and soft drinks. Benzoic acid occurs naturally in many plant and animal products (e.g., milk) at concentrations up to about 40 mg/kg, whereas maximum concentrations of benzoic acid and sodium benzoate in food as preservatives range up to 2,000 mg/kg.[39] Sodium benzoate is conjugated with glycine to form hippurate, which the kidney rapidly excretes in the urine. The administration of sodium benzoate is a treatment for inborn errors of the urea cycle. The dose of sodium benzoate for this disease is 250 mg/kg body weight up to 500 mg/kg daily for several years.[40] The most common adverse responses to this treatment are anorexia and vomiting.[41] However, adverse responses from the use of these doses of sodium benzoate are difficult to separate from the effects of the disease. Table 2 lists recommendations for the storage of selected foods.[42]

Many preservatives, such as sorbates, hydrogen peroxide, benzoic acid (CAS RN: 65-85-0), and sodium benzoate (CAS RN: 532-32-1) cause animal toxicities in extremely high doses; human toxicities primarily involve rare case reports of mild hypersensitivity reactions (urticaria, pruritus).[43,44] Under special circumstances, small amounts of benzene can form from preservative systems comprised of sodium benzoate and citric acid. The decarboxylation of benzoic acid produces measurable amounts of benzene in the presence of transition metals, acid, and heat.[45]

Sulfites

Sulfites, bisulfites, and metabisulfites occur naturally in fermented beverages, such as beer and wine. Similar to food additives, sulfite derivatives are added primarily to packaged fruits, vegetables, and seafood to prevent discoloration. Sulfite-induced hypersensitivity is the most well-established adverse response to a food additive. Four to 8% of asthmatic patients develop sensitivity to sulfites.[46] The hepatic enzyme, sulfite oxidase, catalyzes the conversion of sulfites to inorganic sulfates. Some

TABLE 2.2. Food Storage Recommendations

Food	Fresh (Refrigerated)	Frozen
Beef		
Organs (Liver, Heart)	1 day	1–2 months
Ground	1–2 days	2–3 months
Chops	2–3 days	6–9 months
Steaks	2–3 days	6–9 months
Sausage	2–3 days	1–2 months
Roast	2–4 days	6–12 months
Lunch meats	4–6 days	
Chicken		
Meat	2–3 days	12 months
Liver	1–2 days	3 months
Eggs, fresh	4–5 weeks	Not recommended
Eggs, hard-boiled	1 week	Not recommended
Pork		
Chops	2–3 days	2–3 months
Ground	1–2 days	1–2 months
Roasts	2–4 days	3–6 months
Gravy		1 month
Bread		
Home-made		1 month
Commercial		2–3 months
Butter	1–2 weeks	
Cheese		
Cottage cheese	10–30 days	
Cream cheese (open)	2 weeks	
Processed cheeses	34 weeks	
Ice Cream		2–4 months
Lettuce		
Washed, drained	3–5 days	
Refrigerator crisper	5–7 days	
Mayonnaise	2–3 months in pantry, then refrigerate when open	
Milk	5 days	
Ketchup	12 months in pantry, then refrigerate when open	
Vegetables		
Fresh	1–7 days	
Frozen		8 months

Source: Adapted from Ref 42.

sulfite-sensitive patients lack sulfite oxidase, possibly leading to an accumulation of sulfite and subsequent conversion to sulfur dioxide, a known pulmonary irritant.[47] Some sulfite-sensitive patients have a positive skin test to sulfite, suggesting a relationship with an IgE-mediated response in selected patients. The clinical presentation is an anaphylactic or anaphylactoid reaction with acute bronchospasm. Sulfite sensitivity occurs more commonly in patients with asthma, but sulfite-induced symptoms may develop in patients without documented asthma or other allergy-related disorders. Symptoms include urticaria, angioedema, and IgE-mediated anaphylaxis.[48] Although the FDA banned the use of sulfites on raw foods, sulfites are permitted in processed foods. The presence of sulfites must be declared on food labels if the concentration exceeds 10 ppm, even though sulfite concentrations below 10 ppm in food may trigger reactions.[49] Sulfites are not permitted as additives to foods (enriched flour, produce) high in thiamine (vitamin B_1) because sulfites degrade thiamine.[50]

Nitrates and Nitrites

Nitrates and nitrites are added to hot dogs and other meat products as a method to prevent the growth of *Clostridium botulinum*. Nitrates are reduced to nitrites by enzymes in the mouth and gastrointestinal tract. Nitrites are known oxidative stressors that induce methemoglobinemia in a dose independent fashion.[51] Cases of methemoglobinemia from food exposures occur primarily in infants ingesting home-grown vegetables.[52] Nitrites combine with amine groups to form *N*-nitrosamines in foods that subsequently decompose into free-radical alkyl carbonium ions at physiologic pH. These radicals are mutagenic and carcinogenic in rodents, but studies do not support human carcinogenicity.[12] Although a case control study suggested that salivary nitrate and nitrite concentrations are higher in patients with oral cancer than in controls,[53] epidemiological studies to date have not demonstrated a statistically significant association between dietary exposure to nitrates or nitrites and gastric[54] or colon cancers.[55] In the absence of a definite causal link between nitrate or nitrate exposure and human cancer, the concern over *Clostridium botulinum* control supersedes proposals to reduce nitrate and nitrite additives in food production.[12]

Propionic Acid

Propionic acid is an antifungal agent in floury foods, such as cakes and pastries. The administration of feed containing 4% propionic acid to rats causes an excess of forestomach tumors, when administered during long-term studies.[56] However, the IARC and the US NTP do not list propionic acid as a human carcinogen.

Antibiotics

Antimicrobials including tetracycline, penicillin, and erythromycin are consumed by food-producing animals (e.g., cattle and poultry) to control pathogenic organisms during food production and to promote growth. This

practice results in potential exposure of humans to antibiotic residues in meat, milk, and eggs; however, this level of exposure does not cause human toxicity.[57] A broader, potential risk to human health is the promotion of antibiotic-resistant bacteria by administration of low doses of antibiotics to animals. These bacteria can be transmitted to consumers in contaminated meat as well as in soil, air, and water, when animal manure is added to agricultural fields.[58] Resistant bacterial strains include food borne *Shigella dysenteriae, Escherichia coli, Campylobacter* spp., and *Salmonella* spp. In 1998, 5 patients were hospitalized during an outbreak of *Salmonella typhimurium* DT 104 following ingestion of contaminated pork in Denmark. The same strain of *Salmonella* was detected at a Danish slaughterhouse one month prior to the outbreak, based on molecular fingerprinting. The strain was resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. Subsequently, the outbreak spread to 22 other victims, including a hospital employee and a previously hospitalized patient at the same facility.[59] Similar outbreaks have occurred in Canada and the United States.[60]

Stabilizers and Emulsifiers

Food stabilizers and emulsifiers include lecithin, gelatins, corn starch, waxes, gums, propylene glycol, and cation scavengers such as ethylenediaminetetraacetic acid (EDTA). These agents prevent the natural propensity of food to separate, thin, melt, and precipitate over time. Gums such as guar, carrageenan, cellulose, and xanthan are frequently used in small amounts to stabilize cheeses and to thicken salad dressings and ice cream.[61] In Quebec City, Canada a syndrome of "Beer Drinker's Cardiomyopathy" was described in 1966. Epidemiological analysis of this epidemic revealed numerous beer-drinking patients with congestive heart failure and pericardial effusion. The cause was multifactorial, but the addition of cobalt as a foam stabilizer by microbreweries probably contributed to the cardiotoxicity.[62]

Guar gum is a hydrophilic polysaccharide composed of galactose and mannose (galactomannan). The source of this non-cellulosic, dietary fiber is the endosperm of the Indian clusterbean [*Cyamopsis tetragonoloba* (L.) Taub.]. This bean is an animal food crop in India that contains about 20% guar gum by dry weight.[63] In the presence of water, guar gum forms a highly viscous gel that undergoes fermentation in the colon to short-chain fatty acids. The viscosity of this gel depends on the amount, concentration, and molecular weight of the guar gum. Guar gum is not a uniform product because of variability in the amount of galactomannan cross-linking between different plant sources. Although there is a lack of clinical data, potential uses for this dietary fiber include a dietary supplement for weight reduction, type 2 diabetes, and hypercholesterolemia.[64] Adverse effects result primarily from increased intraluminal pressures and the formation of gas following fermentation. These adverse effects include nausea, diarrhea, and flatulence.[65] Rarely, case reports associate the use of guar gum-containing products with anaphylaxis,[66] occupational asthma,[67] and allergic rhinitis.[68]

Although guar gum-containing tablets are intended to produce a gelatinous mass in the stomach that causes early satiety,[69] numerous case reports associate the use of these tablets with esophageal obstruction, particularly in patients with preexisting esophageal disease (e.g., strictures).[70,71] The use of guar gum in diet pills has been banned in several countries including the United States and Australia as a result of the association of esophageal and small bowel obstruction with the use of these tablets.[72] There is no clear evidence that the long-term use of guar gum causes the permanent weight reduction.[65]

Coloring Agents

Coloring agents are derived from multiple animal, vegetable, and mineral sources, and approximately 10% of all food consumed in the United States contain these compounds.[73] Coloring agents and dyes were commonplace long before experimental testing was performed to document safety. Food producers in the 1800s often used pigments containing heavy metals including arsenic, lead, mercury, thallium, and antimony.[74] Coloring agents are ineligible to appear on the GRAS list; thus, all coloring agents must obtain premarket approval from the FDA before their use in foods. The FDA names synthetic dyes by a food, drug, and cosmetic designation ("FD&C"), followed by a color, and either a number or letter. In the 1950s, the FDA received numerous reports involving the association of candies and popcorn colored with excessive amounts of FD&C Orange No. 1 with acute gastrointestinal distress in children. As a result, the Food, Drug, and Cosmetics Act of 1938 was amended by the Color Additives Amendment of 1960. This legislation allows the FDA to evaluate safety profiles of color additives and limits of all synthetic dyes before marketing. Each manufactured lot or batch of food color must be submitted to the FDA for certification because many food colors are synthesized from highly reactive azo compounds. This process ensures that manufactured lots of color do not contain nonreacted intermediates or toxic side-products from the synthesis of the food colors. FDA chemists evaluate every manufactured batch of color additives for impurities and contaminants that may be carried from their organic sources into the final product.

Each year, the FDA certifies almost 12 million pounds of synthetic color additives and dyes.[73] FDA-certifiable synthetic coloring agents include FD&C Blue No. 1, FD&C Blue No. 2, FD&C Green No. 3, FD&C Red No. 3, FD&C Red No. 40, FD&C Yellow No. 5, FD&C Yellow No. 6, Orange B, and Citrus Red No. 2. Most dyes are sulfonated derivatives of aromatic amines. Sulfonation confers a highly polar moiety to the additive, rendering it poorly absorbable by the gastrointestinal tract. As a result, acute toxicities are not generally observed unless the dyes are present in very large amounts.[75] Concern over dyes and human health effects began in 1959 when reports associated the occurrence of asthma, hypersensitivity, and urticaria with the synthetic aniline dye tartrazine (FD&C Yellow No. 5).[76] Reported symptoms also included migraine, blurred vision, itching, and rhinitis. A double-blind study documented an association between tartrazine and asthma exacerbation in young children,[77] but experimental trials on tartrazine have not conclusively identified a specific clinical syndrome following exposure tartrazine.[78] Since then, dyes have undergone intense evaluation.

Safrole, which occurs naturally in minimal quantities in cinnamon and other spices, was banned as a food additive in 1960 after hepatic and esophageal cancers developed in long-term studies of rats fed safrole. This compound is an alkylbenzene-derivative similar to thujone, which is found in absinthe and oil of wormwood. A reactive metabolite of safrole, 1-hydroxy sulfate ester, is the suspected carcinogen. In 1976, the FDA banned the sale of sassafras tea because of continued detection of safrole as an unavoidable harmful ingredient. Today, safrole-free extracts from sassafras are used as food additives for filé powder and root beer.[79] Amaranth (FD&C Red No. 2) was banned for its association with an increased incidence in embryotoxicity as well as renal pelvis hyperplasia and calcification.[80,81] Lipid-soluble formulations of erythrosine (FD&C Red No. 3) were banned because of the increased incidence of thyroid tumors in male rats fed this dye. Water-soluble derivatives of erythrosine are permitted in foods and oral medications because the gastrointestinal absorption of these compounds is very low.[82,83] FD&C Red No. 4, Green No. 1, Green No. 2, and Violet No. 1 were also banned because of concerns over animal carcinogenesis.[84] As a result of possible carcinogenicity, the use of Orange Number B is restricted to hot dog and sausage casings in concentrations up to 150 ppm of Orange B per food weight. Twenty color additives (e.g., caramel color, fruit juice, chlorophyll, turmeric, dried algae meal, beet juice, paprika) were exempted from FDA certification by the Color Additives Amendment of 1960 because they are extracted from natural sources.[85] Other exemptions include synthetic versions of naturally based compounds (e.g. beta-carotene).[86] Despite these exemptions, natural color additives may still produce adverse responses.[87] Carminic acid (red), annatto (orange), and saffron (yellow) are noncertified dyes that have been associated with IgE-mediated anaphylaxis, urticaria, and angioedema.[88,89]

DIAGNOSTIC TESTING

Sensitivity to food additives is a potential adverse response in patients with sensitivity to multiple, unrelated foods and with negative diagnostic workups for food protein allergies. Meticulous inspection of food labels is the initial approach to detect food sensitivities, but some ingredients are occasionally listed under alternate names. Recent FDA food recall notices are an important source of information. Systematic elimination of foods from the diet may assist the clinician in determining the offending food or additive.

Analytical Methods

Laboratory screening for quantitative IgE antibodies is a nonspecific method to support the presence of food sensitivity. Skin tests are available for coloring agents, sulfites, and other preservatives.[90] Double-blind, placebo-controlled provocative challenges with individual food additives may determine the presence of sensitivity, although challenge doses of most ingredients are not standardized. Provocative challenge tests are frequently used for confirmation of sulfite sensitivity.[91] Food may be analyzed for the presence of any additive; however, this practice is generally limited to epidemiological studies. Methemoglobin concentration is assessed by direct co-oximetry rather than the pulse oximetry used in most clinical settings because the latter method is unable to distinguish methemoglobin from oxyhemoglobin. There are various AOAC International (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) official methods of analysis for intermediates and reaction side-products in specific FDA-approved food colors. For example, AOAC Method 968.17 is a gas chromatographic method for butylated hydroxytoluene and butylated hydroxyanisole in cereals. Cyclamates are detectable in beverages by solid-phase extraction and capillary electrophoresis with indirect ultraviolet detection, and the limits of detection are in the range of 10 μg/g.[92]

Biomarkers

For PKU patients, the long-term goal is to control diet to maintain blood phenylalanine concentrations between

2 and 10 mg/dL to prevent neurologic and neuromuscular sequelae.[93] The vast majority of other sensitivities and adverse responses to food additives are idiosyncratic and dose independent. Therefore, biomarkers for concentrations of additives in humans are not generally used for clinical purposes.

Abnormalities

Normal results of food additive skin tests or IgE concentrations do not rule out sensitivity.[90] Blood phenylalanine concentrations may exceed 100 mg/dL in acute exacerbations of PKU, although phenylalanine concentrations do not consistently correlate to the severity of toxicity. Methemoglobin concentration is reported as a percentage of total hemoglobin. Correlation of methemoglobin concentrations to cyanosis depends on the total amount of hemoglobin present.

TREATMENT

Patients with confirmed sensitivities to food additives should avoid foods with these additives under the guidance of an allergist and a clinical dietician. Newborns are screened for PKU routinely in every US state, and families with affected newborns are counseled to avoid excess intake of foods containing phenylalanine and related compounds.[94] Patients with sensitivities require education regarding the potential for unlisted ingredients and proper interpretation of food labels, and these patients should wear medical alert identification tags at all times. Antihistamines are adequate to treat mild hypersensitivity symptoms such as itching, urticaria, and rhinitis. Certain patients with mild, predictable reactions may benefit from daily prophylaxis or pretreatment with antihistamines to tolerate offending food ingredients.[95] Patients with recalcitrant or persistent symptoms may benefit from corticosteroid therapy under the guidance of an allergist. Bronchodilators are used to treat bronchospasm and related pulmonary symptoms. Asthmatic patients with food sensitivity should carry rescue inhalers at all times; patients with history of severe responses may also need to carry rapid self-injectable epinephrine devices.[96] Decontamination of a patient by cleansing the lips and hands for residual deposits of the offending food is a reasonable approach, but there are inadequate epidemiologic data to demonstrate that this practice improves clinical outcome. Anaphylaxis and anaphylactoid reactions are treated by standard advanced life support protocols.[97] Methemoglobinemia is treated with supportive care, supplemental oxygen, and methylene blue in moderate-to-severe cases. Desensitizing immunotherapy has not been evaluated for food additive sensitivity.

Chapter 3

AKEE FRUIT and JAMAICAN VOMITING SICKNESS (*Blighia sapida* Köenig)

HISTORY

Blighia sapida Köenig is a native plant of West Africa that was introduced to Jamaica in 1776 by Thomas Clark.[1] The infamous Captain Bligh took the breadfruit tree to the West Indies.[2] Toxicity has been associated with the consumption of unripe akee fruit since the late 19th century.[3] Between 1880 and 1955, a variety of case reports associated the ingestion of akee fruit with vomiting, generalized weakness, altered consciousness, and death including an epidemic of 151 cases and 32 deaths during 1954 near Montego Bay, Jamaica.[1] Hassal et al first isolated the two toxic constituents (hypoglycin A and B) from the arils and seeds of unripe akee in 1954.[4] In 1976, Tanaka et al confirmed the ingestion of hypoglycin A from unripe akee fruit as the cause of Jamaican vomiting sickness.[5]

BOTANICAL DESCRIPTION

Common Name: Akee tree

Scientific Name: *Blighia sapida* Köenig

Botanical Family: Sapindaceae (soapberry)

Physical Description: The akee tree is a tropical evergreen tree with broad, pinnate leaves. The tree bears an oblong-shaped, yellow-red fruit that is about 10 cm (4 in.) wide and weighs 100 g. As the akee fruit ripens, the color of the fruit changes from green to yellow, to yellow-red, and then to red. When ripe, the fruit splits longitudinally into three sections to reveal glassy black seeds in each section surrounded by a thick oily aril.

Distribution and Ecology: The akee tree is a native species of West Africa, which was introduced into Jamaica and has naturalized in southern California and Florida, as well as the Antilles, and Central America. Consumption of the akee fruit is uncommon outside these areas with the exception of the illicit importation of this fruit into countries with a ban on akee fruit. Figure 3.1 displays a specimen of the akee fruit.

EXPOSURE

The ripe fleshy akee aril is a food staple among poor Jamaican and West African children. The akee is the national fruit of Jamaica. Although akee fruit is banned from commerce in the United States, canned akee fruit is available in the Caribbean Islands.[6] To prevent toxicity, the seeds and membrane of the akee fruit must be carefully removed and the aril thoroughly washed before consumption.

PRINCIPAL TOXINS

Physiochemical Properties

Ingestion of unripe akee fruit causes Jamaican vomiting sickness. The unripe fruit contain a water-soluble toxin, hypoglycin A (L-α-aminomethylenecyclopropylpropionic acid) and the less toxic hypoglycin B. The latter compound is the γ-glutamyl conjugate of hypoglycin A. Unripe akee fruit also contain glutamate analogs that are carboxycyclopropylglycine compounds.[7] Cooking *unripe* akee fruit does not destroy the toxins in these

FIGURE 3.1. Akee fruit. Photograph courtesy of Stephan Russ. See color insert.

fruit, whereas cooking effectively eliminates the toxicity of the *ripe* fruit by leaching hypoglycin A from the ripe fruit.[6,8]

Poisonous Parts

The akee fruit and the white aril surrounding the seeds are edible only when the fruit spontaneously opens (i.e., stage 8 of the 10-stage maturity scale assigned to akee fruit).[9] This maturity scale ranges from stage 1 (blossom development with very small fruit) to stage 10 (the onset of spoilage with decay of the aril). Full maturity (i.e., stage 8) of the akee fruit occurs when the red or yellow pod is completely open with the seed and aril clearly exposed. The concentration of hypoglycin A is substantially higher in unripe than ripe akee fruit, and the hypoglycin A content of the aril decreases substantially as the fruit ripens. In uncooked samples of akee fruit, the hypoglycin A content in unripe and ripe fruit was approximately 124 ± 7 mg/100 g fresh weight and about 6 ± 1 mg/100 g fresh weight, respectively.[10] In another study, the concentration of hypoglycin A decreased from 711 mg/100 g in raw, unripe fruit to below the limits of detection (1.2 mg/100 g) in the ripe aril, as measured by ion-exchange chromatography.[11] The concentration of hypoglycin A in the membrane and aril is similar as the fruit matures, but the membrane contains detectable amounts (i.e., <40 ppm) of hypoglycin A even at the edible stage.[9] The ripe aril does not usually contain detectable amounts of hypoglycin B.

The concentration of hypoglycin A remains relatively constant in the seeds until maturation. The husk and seeds of the fresh akee fruit retain significant concentrations of hypoglycin A as the fruit matures.[12] The seeds contain several times higher concentrations of hypoglycin A than unripe akee aril. In a study of akee fruit from a Florida subtropical horticulture research station, the hypoglycin A content decreased from 939 mg/100 g in unripe seeds to 269 mg/100 g in ripe seeds, whereas the hypoglycin A content in the husk remained near 40 mg/100 g.[11] The hypoglycin A content in canned akee fruit is variable. In six samples of commercially canned akee fruit, the hypoglycin A content in the drained solid or edible portion of the six samples ranged between 11 mg and 66 mg with a mean of 35.6 mg.[13] The mean weight of the solid portion of the six samples was approximately 378 ± 13 g. The liquid portion of the samples accounted for about one-third of the weight of the contents, and the mean hypoglycin A content in the liquid portion of the six cans was 20.4 g with a range between 7.8 g and 38.7 g. Akee oil is the lipid fraction of the unripe akee aril and the yield of akee oil is >60% wet weight.

Mechanism of Toxicity

Metabolism of hypoglycin A produces methylenecyclopropylacetic acid, which reduces several cofactors (e.g., coenzyme A, carnitine) essential to the β-oxidation of long-chain fatty acids and inhibits the transport of long-chain fatty acids into the mitochondria.[14,15] Consequently, fatty acids conjugated with carnitines (e.g., octanoylcarnitine) accumulate in the serum and urine. Accumulation of short-chain fatty acids (e.g., propionic, *n*-butyric, isovaleric acid) in the serum results from the suppression of short-chain acyl-CoA dehydrogenases and β-oxidation. Long-chain fatty acids undergo omega-oxidation by mixed function oxidases in the endoplasmic reticulum of the liver as a result of the impairment of β-oxidation, and accumulation of short- and medium-chain dicarboxylic acids (e.g., glutaric, ethylmalonic acid) occurs in the urine. The reduction in fatty acid metabolism causes an increased use of glucose, and the blockade of the substrate for hepatic gluconeogenesis causes hypoglycemia after the depletion of NADH and hepatic glycogen stores. However, hypoglycemia does not explain the entire clinical picture because vomiting and central nervous system (CNS) depression occur during intoxication without the presence of hypoglycemia.[16] Although the increased concentration of short-chain fatty acids (e.g., isovaleric, 1-methylbutyric acids) may contribute to the metabolic acidosis present during severe akee poisoning, the concentrations of these fatty acids are too low to cause lethargy and coma.[5] The potential involvement of glutamate analogs (i.e., carboxycyclopropylglycine compounds) may account for some of the CNS effects present during Jamaican vomiting sickness.[17]

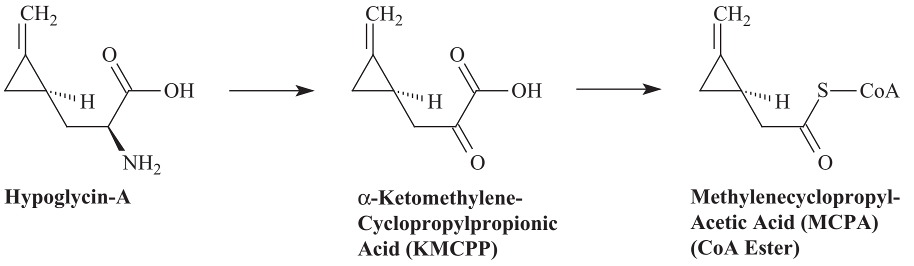

FIGURE 3.2. Metabolism of hypoglycin to the toxic metabolite.

Pathophysiology

The intraperitoneal administration of the lipid portion of unripe akee fruit (i.e., akee oil) to rats produces petechial hemorrhages and perivascular mononuclear infiltrates in the lungs, probably as a result of a hypersensitivity reaction.[18] Similar reactions in humans following the consumption of akee fruit have not been documented in the medical literature. Findings upon postmortem examination of fatal akee fruit intoxications include fatty metamorphosis of the liver and kidney, depletion of liver glycogen, diffuse petechial hemorrhages, and generalized hyperemia of the internal organs.[2] Pathological changes in the liver are similar to the histological abnormalities associated with Reye's syndrome and impila toxicity.[19]

Toxicokinetics

The metabolic pathway for the biotransformation of hypoglycin A and other branched-chain amino acids is similar. Metabolism of hypoglycin A produces the toxic metabolite, methylenecyclopropylacetic acid (MCPA-CoA), which inhibits the oxidation of long-chain fatty acids leading to hypoglycemia. α-Ketomethylenecyclopropylpropionic acid is an intermediate metabolite of hypoglycin A as demonstrated by Figure 3.2. The kidneys excrete un-reacted MCPA-CoA as methylenecyclopropyl-acetyl-glycine.[20] Urine specimens from two children with akee fruit poisoning contained substantial amounts of methylenecyclopropylacetic acid as well as the medium-chain dicarboxylic acids, 2-ethylmalonate, adipate, and glutarate.[21]

DOSE RESPONSE

The ingestion of 12 and 24 uncooked, raw akee fruit by two adults produced vomiting and drowsiness that progressed to mild hypoglycemia and coma.[8] Within 2–3 days after ingestion, respiratory depression required endotracheal intubation for respiratory support, but within about one week recovery was complete. In a study of male and female rats, the acute toxic dose for male and female rats was 231.19 ± 62.5 5 mg hypoglycin A/kg body weight and 215.99 ± 63.33 mg hypoglycin A/kg body weight, respectively.[22] This study used the World Health Organization definition of acute akee toxicity (impairment of movement, raised hairs, arched backs, 10% loss of body weight, and black feces). The maximum tolerated daily dose of hypoglycin A over the 30-day study was 1.50 ± 0.07 mg hypoglycin A/kg body weight.

CLINICAL RESPONSE

The syndrome of Jamaican vomiting sickness is similar to Reye's syndrome and is characterized by gastrointestinal distress, hypoglycemia, and CNS depression.[23] Symptoms typically develop within 6–48 hours after ingestion of unripe akee fruit with symptoms occasionally occurring within 2 hours of ingestion.[24] Hypotonia and seizures occur commonly in severe cases of Jamaican vomiting sickness, particularly in young children. Nausea, vomiting, and abdominal pain are usually, but not always, the initial symptoms. These gastrointestinal symptoms appear within several hours after ingestion of unripe akee fruit.[25] Other initial symptoms of akee poisoning include headache, thirst, and paresthesia.[6] Lethargy, hypotonia, hypothermia, convulsions, and coma occur after a brief quiescent period followed in some cases by death up to 48 hours after ingestion. Fever usually is absent and death is more common in children than in adults.[26] A case report suggests that chronic exposure to unripe akee fruit produces cholestatic jaundice characterized by jaundice, pruritus, diarrhea, and right upper quadrant abdominal pain.[27] However, the liver biopsy demonstrated cholestasis and centrilobular necrosis, which are atypical of histological changes associated with Jamaican vomiting sickness. Rarely, case reports associate the development of hypersensitivity reactions (urticaria, angioedema, chest tightness, brief syncope) with the ingestion of akee fruit by patients with known histories of food allergies or anaphylaxis.[28]

DIAGNOSTIC TESTING

Analytical Methods

Methods for the determination of hypoglycin A content of akee fruit include ion exchange chromatography (IEC)[13] and reversed phase high performance liquid chromatography with UV detection at 254 nm (RP/HPLC/UV).[29] The precision and accuracy of HPLC/UV is sufficient to determine hypoglycin A concentrations in a range between 50 µg/g and 400 µg/g akee fruit, whereas the limit of detection for IEC is about 5 µg/mL.

Biomarkers

The metabolism of hypoglycin A is rapid, and therefore this compound is not usually detectable in biological samples from affected patients. The presence of the metabolite of hypoglycin A (methylenecyclopropylacetic acid) is a biomarker of exposure to akee fruit.[5] The inhibition of acetyl CoA enzymes increases serum carboxylic acids and the renal excretion of dicarboxylic acids with 5–10 carbons (propionic, isobutyric, *n*-butyric, isovaleric, *n*-hexanoic, glutaric, adipic, suberic, sebacic). Adipic acid and lactic acid occur commonly in urine samples of patients poisoned with unripe akee fruit.[8] Although the hypoglycin A concentration is usually nondetectable in postmortem samples from patients dying of Jamaican vomiting sickness, urinary concentrations of organic acids are typically elevated including adipic acid, glutaric acid, and suberic acid.[24] Increased urine concentrations of glutaric and ethylmalonic acids occur only after ingestion of hypoglycin A and a rare genetic disorder (type II glutaric aciduria).[30] Additionally, the concentrations of some carnitine compounds are elevated in serum and urine samples from affected patients, particularly octanoylcarnitine and the metabolite, hexanoylcarnitine.[24]

Abnormalities

In addition to severe hypoglycemia, serious intoxication laboratory abnormalities include metabolic acidosis, electrolyte imbalance (e.g., hypokalemia), and laboratory evidence of dehydration (e.g., elevated serum BUN to creatinine ratio).

TREATMENT

Decontamination measures are usually unnecessary because of the prominence of vomiting and the late presentation (i.e., >1 hour after ingestion). All symptomatic patients should receive measurements of serum glucose, serum electrolytes, and arterial pH. The presence of any degree of obtundation mandates immediate bedside analysis of the serum glucose concentration and the intravenous administration of glucose as needed. The serum glucose should be monitored serially, particularly when the mental status deteriorates, along with serum hepatic aminotransferases and serum creatinine. Treatment is primarily supportive with restoration of fluid, electrolyte, glucose, and pH balance. Experimental studies suggest that glycine[31–32] and methylene blue[33] are potential treatments for akee fruit poisoning, but there are no clinical data to support the efficacy of these agents during akee fruit poisoning, particularly when administered more than several hours after ingestion. An *in vitro* study of rat hepatocytes did not support the use of carnitine as an antidote for the inhibition of multiple acyl-CoA dehydrogenase enzymes following the consumption of unripe akee fruit.[34]

Chapter 4

CINNAMON
(*Cinnamomum* Species)

HISTORY

Cinnamon has been used as a spice for thousands of years; several references to it are found in the Bible. In Egypt, cinnamon was a spice used in embalming fluid. In Ayurvedic medicine, cinnamon bark was used as an antiemetic, antidiarrheal, antiflatulent, and general stimulant. The Portuguese found cinnamon trees growing in Sri Lanka (Ceylon) during the early 16th century; they subsequently imported cinnamon to Europe during the 16th and 17th centuries. The Dutch occupied Sri Lanka in the mid-17th century until the British captured the island in 1796. The East India Company then became the main exporter of cinnamon to Europe. The Dutch cultivated cinnamon in Java, and the exports of Ceylon cinnamon decreased as a result of heavy export duties. Nevertheless, Sri Lanka is the only regular supplier of cinnamon bark and leaf oils. The food industry prefers Ceylon cinnamon, but pharmaceutical manufacturers use both oils from Ceylon cinnamon (cinnamon oil) and from Chinese cinnamon (cassia oil) interchangeably. China is the main exporter of cassia oil.

BOTANICAL DESCRIPTION

The genus *Cinnamomum* comprises over 250 aromatic evergreen trees and shrubs, primarily located in Asia and Australia.

Common Name: Cinnamon, Ceylon cinnamon

Scientific Name: *Cinnamomum verum* J. Presl (*Cinnamomum zeylanicum* Blume, *Laurus cinnamomum* L.)

Botanical Family: Lauraceae (laurel family)

Physical Description: Large evergreen trees with young branches that are smooth and brown. The leaves are opposite, leathery, ovate to broadly ovate with three (and rarely, five) prominent veins. Young leaves are reddish and later turn dark green. Small, pale yellow flowers are borne in axillary or terminal panicles. The fruit is a fleshy, ovoid drupe, which contains one seed and turns dark purple or black when ripe.

Distribution and Ecology: Ceylon cinnamon is an indigenous tree of Sri Lanka and southwestern India.

Common Name: Cassia, Chinese cinnamon, false cinnamon, cassia lignea, bastard cinnamon, cassia bark, cassia-bark tree, Chinese cassia, Saigon cinnamon

Scientific Name: *Cinnamomum aromaticum* Nees (*Cinnamomum cassia* Nees ex Blume, *Cinnamomum cassia* J. Presl)

Botanical Family: Lauraceae (laurel family)

Physical Description: This slender, evergreen tree grows up to 65 ft (20 meters) high. Young branches are smooth and brown. The leaves are subopposite, slender, lanceolate or oblanceolate with three prominent veins. These leaves are reddish when young and dark green when mature. The small, white flowers are borne in axillary or terminal panicles. The fruit is a green, fleshy, globose drupe, which contains one seed and turns dark purple or black when mature. This fruit is similar in size to a small olive.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Distribution and Ecology: Chinese cinnamon is an indigenous bush in the mountains of southern China, and cultivation for cassia oil production now occurs primarily in the southern Chinese provinces of Guangxi (Kwangsi) and Guangdong (Kwangtung). Other similar species occur on the Indonesian islands of Sumatra and Java [*C. burmannii* (Nees & T. Nees) Blume, Indonesia cassia], in Vietnam (*C. loureiroi* Nees, Vietnamese cassia), and in India and Nepal [*C. tamala* (Buch.-Ham.) Nees & Eberm., Indian cassia]. Commercial cultivation of these cassia species occurs in all of these areas.

EXPOSURE

Sources

Cinnamon leaf and bark are spices and sources of cinnamon oil, primarily from the *Cinnamomum verum* J. Presl (Ceylon cinnamon). However, most of products are extracted from cinnamon trees cultivated at altitudes up to about 1500 ft (460 meters). Cortex cinnamomi is the dried inner bark of shoots from *Cinnamomum verum* J. Presl or the stripped trunk bark of *Cinnamomum cassia* Blume. *Cinnamomum aromaticum* Nees (Chinese cinnamon) is the main source of internationally traded cassia oil, which is a distillate from a mixture of leaves, twigs, and bark fragments. Limited commercial production of cassia oil occurs in other regions including Indonesia [*C. burmannii* (Nees & T. Nees) Blume], Vietnam (*Cinnamomum loureiroi* Nees), and India [*C. tamala* (Buch.-Ham.) Nees & Eberm.].

Commercial production of cinnamon usually begins about 3–4 years after planting and pruning of the stems to force the growth of young stems. These stems are cut during the rainy season to facilitate the peeling of the bark. After scraping the outer skin of the bark, workers rub off the bark with a brass block. The bark is then split from end to end with a special round knife. The long strips of bark are then formed into the familiar compound quills (cinnamon) or hollow quills (cassia) of the spices that are stuffed with fragments of bark and then dried. Bleaching with sulfur dioxide disinfects the material and imparts a golden hue to the quills.

Uses

Traditional

The herbal use of cinnamon includes application as an astringent, germicide, and antispasmodic. Cinnamon was one of the early treatments for chronic bronchitis.[1] Other traditional uses include the treatment of impotence, frigidity, dyspnea, inflammation of the eye, leukorrhea, vaginitis, rheumatism, and neuralgia, as well as wounds and toothaches.[2]

Current

Cinnamon *bark* oil has a delicate aroma along with a sweet, pungent taste that results in use primarily as a flavoring in dental and pharmaceutical preparations, seasonings, sauces, baked goods, drinks, and tobacco. Investigational uses of cinnamon bark include use as a hypoglycemic and cholesterol lowering agent,[3] promotion of wound healing,[4] antimicrobial agent,[5] and an antiinflammatory compound.[6] The flavoring agent cinnamaldehyde in cinnamon oil is added to toothpaste to mask the taste of pyrophosphate, which is an unpleasant tasting compound that inhibits plaque calcification by interrupting the conversion of amorphous calcium phosphate to hydroxyapatite. The skin sensitizing properties of cinnamon bark oil limits use of this essential oil in cosmetic and other topical products.[7] Cinnamon *leaf* oil has a warm, spicy, and somewhat harsh odor that lacks the smooth consistency of cinnamon bark oil. Major uses of this essential oil include as flavoring in seasonings and a fragrance in soaps and insecticides. Cinnamon leaf oil is also a source for eugenol. Cassia oil is used medicinally as a carminative, antidiarrheal, antimicrobial, and antiemetic. Traditional uses for dried cassia include digestive complaints such as flatulence, colic, dyspepsia, diarrhea, and nausea, as well as colds, influenza, fevers, arthritis, and rheumatism. The major commercial uses of cassia oil are the flavoring of cola-type drinks and, to a lesser extent, bakery goods, sauces, confectionery products, and liquors. Like cinnamon bark oil, the use of cassia oil in topical preparations is limited by its skin-sensitizing properties. Cassia oil is a constituent of tiger balm. Smoking cessation products frequently involve the use of candies, chewing gum, or fresheners that often contain cinnamon flavoring. A few clinical studies suggest that cinnamon supplementation may lower blood glucose concentrations in patients with diabetes type 2; however, the sample sizes of these studies were small and there are inadequate data to recommend the regular use of cinnamon in diabetic patients.[8]

Regulatory Status

In the United States, cinnamon has GRAS (generally recognized as safe) status as a food additive.

PRINCIPAL TOXINS

Chemical Composition

Volatile oils are distilled products from the bark, leaves, flowers, or buds of *Cinnamomum* species, and the chemical composition of these oils varies depending on the part of the plant used for the distillation process. Cinnamon bark and leaf oil are steam distillation products obtained from the inner bark and leaves, respectively, of Ceylon cinnamon (*Cinnamomum verum*).[9] Other sources of cinnamon include Japanese cinnamon, Java cinnamon, and Taiwan cinnamon. Most of the chemical constituents of the essential oils from cinnamon are monoterpenes, sesquiterpenes, and related oxygen derivatives of these two types of compounds. The major monoterpene hydrocarbons in volatile components of cinnamon extracts are α-pinene, camphene, and limonene.[10] The main constituent of cinnamon *bark* oil is cinnamaldehyde (Figure 4.1), whereas eugenol is the main constituent (i.e., about 81–85%) of cinnamon leaf oil.[11] A commercial sample of essential oils from *Cinnamomum verum* contained approximately 63% cinnamaldehyde, 8% limonene, 7% eugenol, 5.5% cinnamaldehyde propylene, and <1–2% of a variety of terpenoid compounds (α-pinene, camphene) as measured by gas chromatography/mass spectrometry.[5] Cinnamon *leaf* oil contains a variety of constituents including eugenol (CAS RN: 97-53-0, $C_{10}H_{12}O_2$) and cinnamaldehyde (CAS RN: 104-55-2, C_9H_8O), which is a local mucous and dermal membrane irritant. In a study of the essential oils from leaves of *Cinnamomum osmophloeum* (Taiwan cinnamon), terpenoid compounds accounted for approximately 90% of the chemical compounds with 1,8-cineole, spathulenol, santolina triene, and caryophyllene oxide being the most common compounds.[6]

The essential oils from leaves of *Cinnamomum* species accounts for about 0.5% dry weight. Analysis of a steam-distilled volatile oil from cinnamon fruit stalks yielded 27 compounds with cinnamyl acetate (36.59%) and caryophyllene (22.36%) being the major components.[12] Analysis of the hydro-distilled volatile oil from buds of *Cinnamomum verum* (*C. zeylanicum*) yielded terpene hydrocarbons (78%) and oxygenated terpenoids (9%) with the sesquiterpenes, α-bergamotene (27%) and α-copaene (23%), being the most common compounds.[13] Minor compounds included α-humulene, α-muurolene, and δ-cadinenes. The volatile oil of the buds contains more monoterpene and sesquiterpene compounds than oils from the flowers and fruits, whereas the concentration of *trans*-cinnamyl acetate is much higher in the volatile oils from flowers and fruit than from the buds. A study of cinnamon essential oil from *C. verum* grown in Madagascar indicated that the major constituent was *trans*-cinnamaldehyde (41.3%).[14] Cassia oil is extracted from the leaves, bark, twigs, and stalks of *C. cassia* by steam distillation.

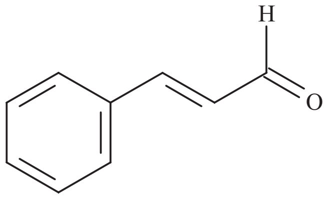

FIGURE 4.1. Chemical structure of cinnamaldehyde.

Physicochemical Properties

Cinnamon leaf oil has a fragrant odor and a very pungent taste. Experimental studies suggest that cinnamon has some mosquito larvicidal activity[15] and some antibacterial properties when added to certain food products.[16] However, there is no conclusive evidence that the antimicrobial properties of cinnamon produce clinically efficacious results.[17] Table 4.1 lists some of the physical properties of cinnamaldehyde.

DOSE RESPONSE

Medicinal Use

The average daily dose of the crude drug (cortex cinnamomi) is 2–4 g or 0.05–0.2 g of the essential oil.

Toxicity

The ingestion of an estimated 60 mL of cinnamon oil was associated with burning sensation in the gastrointestinal tract along with lethargy, double vision, vomiting, and lightheadedness.[18] The symptoms resolved spontaneously within 5 hours with no complications.

TABLE 4.1. Some Physical Properties of Cinnamaldehyde

Physical Property	Value
Melting point	−7.50°C
Boiling point	246°C
log P (octanol-water)	1.9
Water solubility	1420 mg/L (25°C)
Henry's Law Constant	1.60 E-06 atm m^3/mole (25°C)
Atmospheric OH rate constant	3.79 E-11 cm^3 molecule/second (25°C)

TOXICOKINETICS

There are few human toxicokinetic data for the constituents in cinnamon oil. Rodent studies indicate that the major metabolic pathway of *o*-methoxycinnamaldehyde involves oxidation to the corresponding cinnamic and phenylpropionic acids with subsequent urinary excretion of benzoic and hippuric acids.[19]

CLINICAL RESPONSE

Most case reports of toxicity from cinnamon oil involve local irritation and allergic reactions to cinnamon oil as a constituent of personal hygiene (toilet soaps, mouthwash, toothpaste, perfumes, mud baths),[20] beverages (colas, vermouth, bitters), or baking products.[21–23] Allergic reactions include contact dermatitis, perioral dermatitis, cheilitis, stomatitis, gingivitis, glossitis, chronic lichenoid mucositis, contact urticaria,[24] and rarely immediate hypersensitivity reactions (asthma, urticaria).[25,26] Clinical manifestations of intraoral reactions include pain, swelling, erythema, ulcerations, fissures, vesicles, and white patches.[27] These reactions are local, and distal skin involvement is rare.[28] Occupational allergic contact dermatitis from spices is rare, and typically involves the hands.[29] More common food sensitizers include carrot, cucumber, tomato, melon, fish, potato, orange, green pepper, onion, red cherry, and garlic. Cinnamon oil contains local mucous membrane irritants such as cinnamaldehyde and cinnamic acid. Prolonged skin contact (48 hours) from a cinnamon oil spill produced superficial partial-thickness burns.[30] Chronic use of cinnamon-flavored gum can produce submucosal inflammation and alteration of the surface epidermis resembling oral leukoplakia, manifest on biopsy by acanthosis, hyperkeratosis, parakeratosis, plasma cell infiltration, fibrosis of the lamina, and focal atypia.[31] These changes are not pathognomonic for cinnamon-induced mucositis. The differential diagnosis of chronic mucositis associated with hypersensitivity to cinnamon includes local trauma, smokeless tobacco keratosis (snuff dipper's lesion), hyperkeratosis, lichen planus, lupus erythematosus, candidiasis, premalignant lesions, lichenoid mucositis, and carcinoma.

The severity of the local mucosal reaction depends on the duration of cinnamon-gum chewing. In contrast to the diffuse gingival reaction associated with cinnamon-flavored toothpaste, oral lesions associated with gum chewing occur on the lateral border of the free tongue or adjacent buccal mucosa. Sequelae of contact dermatitis associated with cinnamon include desquamation and hyperpigmentation.[32] Although a case report associated the development of squamous cell carcinoma of the tongue with prolonged use of cinnamon gum,[33] the International Agency for Research on Cancer (IARC) and the US National Toxicology Program do not list cinnamon as a potential carcinogen.

School-aged children abuse cinnamon oil by sucking on toothpicks or fingers dipped in the oil.[34] Reported effects include facial flushing, sensation of warmth, and intraoral hyperesthesias. Although nausea and abdominal pain may occur, systemic symptoms do not usually result from this type of exposure. Ingestion of cinnamon oil may cause central nervous system depression, predisposing the patient to aspiration pneumonia.

DIAGNOSTIC TESTING

Analytical methods for the identification of the constituents of cinnamon oil include high performance liquid chromatography[35] and gas chromatography/mass spectrometry.[10,36]

TREATMENT

Treatment is supportive. Patients with leukoplakia after chronic use of cinnamon-containing gums should be observed for resolution after cessation of use. Persistent oral lesions should be evaluated for oral cancer.

Chapter 5

CYANOGENIC FOODS
(Cassava, Fruit Kernels, and Cycad Seeds)

HISTORY

Cassava is a staple in Africa that contains toxic concentrations of cyanogenic glycosides when improperly processed. Occasionally, outbreaks of cyanide poisoning occur following the consumption of bitter cassava, particularly during periods of drought.[1]

BOTANICAL DESCRIPTION

The distribution of cyanogenic glycosides is widespread throughout the plant kingdom, occurring in at least 2,500 plants species, primarily in the Compositae, Fabaceae, Linaceae, and Rosaceae families.[2] Of these plants, clinically important human toxicity probably occurs only following the ingestion of cassava. Prunasin occurs in at least six plant families (Myoporaceae, Myrtaceae, Polypodiaceae, Rosaceae, Saxifragaceae, Scrophulariaceae).

Cassava

Common Name: Cassava

Scientific Name: *Manihot esculenta* Crantz

Botanical Family: Euphorbiaceae (Spurge)

Physical Description: Cassava is a perennial, woody shrub with large, brown, tapered tubers that are staples in many poor countries. This shrub or small tree reaches about 1.25–5 m (4–16 ft) in height. The leaves are glabrous and deeply parted with spatulate to linear-lanceolate acuminate lobes up to 15 cm (6 in.) long. The flowers form panicles.

Distribution and Ecology: This plant is a native species of Central and South America that was spread by 17th century explorers to Africa and later to the Indian subcontinent. Cassava is widely cultivated in subtropical and tropical areas for the high starch content of the tubers.

Fruit Kernels (*Prunus spp.*)

Common Name: Apple

Scientific Name: *Malus domestica* Borkh.

Botanical Family: Rosaceae (rose)

Physical Description: This deciduous fruit tree forms a broad crown and reaches up to 12 m (39 ft) in height. The leaves are simple and alternate with a serrated tip and petiole up to 5 cm (2 in.) long. The white flower appears in spring with five petals. The fruit matures in autumn with five, star-shaped carpels containing one or two seeds.

Distribution and Ecology: The apple is a native plant of the mountains in Central Asia, and now numerous cultivars of the apple are widely distributed throughout the world.

Common Name: Peach

Scientific Name: *Prunus persica* (L.) Batsch.

Botanical Family: Rosaceae (rose)

Physical Description: The deciduous tree reaches up to 10 m (33 ft) in height with broad, lanceolate leaves up to 15 cm (6 in.) long. In early spring, the solitary, pink flowers appear before the leaves with five petals. The drupe (stone fruit) contains a single, large seed with a hard, corrugated cover.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Distribution and Ecology: This peach tree is a native species of China, which is now widely cultivated in temperate climates. However, the chilling requirements and limited cold tolerance of the fruit restricts the areas of production to places other than tropical and subtropical climates.

Cycad Seeds

Cycas plants (e.g., *Cycas revoluta* Thunb. or sago palm) belong to the order Cycadales, which contains approximately 11 genera of tropical and subtropical plants that produce terminal oblong cones containing orange-yellow seeds. This slow growing fern-like tree is a native species of southern Japan, but this plant has been naturalized throughout temperate and tropical habitats.

EXPOSURE

Cyanogenic glycosides in economically important plants include linamarin in *Manihot esculenta* Crantz (cassava), *Linum usitatissimum* L. (flax), and *Trifolium repens* L. (white clover); lotaustralin in *Lotus corniculatus* L. (bird's foot trefoil); dhurrin in *Sorghum* spp.; and amygdalin in Rosaceae species (peach, apricot, apple seeds).[2] Medicinal uses of fruits from the genus *Prunus* include the treatment of headache, hypertension, diarrhea, and constipation.[3] Cassava tuber is an important food source with high carbohydrate and low protein content for up to 500 million people in tropical Africa and Latin America.[4] Although millet, rice, and potatoes are usually preferred food sources, cassava root is a cheap source of energy, particularly during difficult economic times. Gari is a grit derived from the cassava root by grating, dehydrating, and fermenting the root pulp and then roasting the resultant mash. Eba is a paste formed from the addition of boiling water to gari. The Cycas plant has a long history of use as a food and medicine.[5] In traditional Chinese medicine, cycad seeds are used to treat hypertension, musculoskeletal disorders, gastrointestinal distress, cough, and amenorrhea.

PRINCIPAL TOXINS

Structure and Properties

Cyanogenic glycosides are secondary plant metabolites composed of an α-hydroxynitrile aglycone and a sugar moiety (e.g., D-glucose). Many of these cyanogenic glycosides are structurally similar to prunasin including amygdalin (Rosaceae), sambunigrin (Caprifoliaceae, Mimosaceae, Oleaceae), and vicianin (Fabaceae, Polypodiaceae) as demonstrated in Table 5.1. The biosynthetic precursors of cyanogenic glycosides in these plants are various L-amino acids that are hydroxylated to *N*-hydroxylamino acids, aldoximes and then to nitriles. Linamarin and lotaustralin are derivatives of valine, isoleucine and leucine, whereas prunasin, amygdalin, and sambunigrin are derivatives of phenylalanine.[6] Dhurrin is a tyrosine derivative. Hydroxylation of nitriles to α-hydroxynitrile followed by glycosylation forms the cyanogenic glycosides. The initial metabolism of cyanogenic glycosides involves the cleavage of the carbohydrate moiety by one or more β-glycosidases that yields the corresponding α-hydroxynitrile.[7] Hydroxynitrile compounds may decompose either spontaneously or enzymically in the presence of a hydroxynitrile lyase to produce hydrogen cyanide and an aldehyde or ketone. The separation of cyanogenic glycosides and the degrading enzymes in the plant tissues prevents the formation of significant amounts of cyanide until the physical disruption of the plant compartments.

Fruit Kernels

The seeds of stone fruits from *Prunus* species (e.g., cherries, peaches, apricots) contain up to 6% amygdalin on a fresh weight basis, whereas the cyanogenic glucoside content of the pulp ranges from about 0.001–0.01%.[8] Consequently, canned stone fruits can contain small amounts (i.e., up to 4 mg/kg) of hydrogen cyanide. Amygdalin is the cyanogenic diglucoside, D-mandelonitrile-β-D-gentiobioside, present in the kernels of many stone fruits. Amygdalin hydrolase and prunasin hydrolase are two β-glycosidases that catalyze the hydrolysis of amygdalin in a stepwise reaction by removing two glucose residues and releasing benzaldehyde and hydrogen cyanide.[9] These enzymes are released following the crushing of moistened, amygdalin hydrolase-containing kernels. Amygdalin hydrolase removes the terminal glucose of amygdalin and forms the monoglucoside, prunasin. Certain human intestinal bacteria may also possess glycosidase activity, so that ingestion of amygdalin in the absence of this plant enzyme can cause cyanide toxicity. *In vitro* studies indicate that the addition of β-glucuronidase to amygdalin does not liberate hydrogen cyanide.[10] In addition to amygdalin and prunasin, peach seeds also contain several minor cyanogenic glycosides including amygdalinic acid, mandelic acid β-D-glucopyranoside, benzyl β-gentiobioside, and benzyl β-D-glucopyranoside.[11]

Cassava

Linamarin and the methyl derivative, lotaustralin, are the two main cyanogenic glycoside compounds in cassava root-derived foods, while the content of hydrogen cyanide and cyanohydrins are generally low.[12,13]

TABLE 5.1. Chemical Structure of Common Cyanogenic Glucosides

Base Structure	Substituent R	Glycoside	Sugar	Occurrence
Glycosides with aromatic substituents				
	Phenyl	Prunasin	D-Glucose	*Prunus* spp.
	Phenyl	Amygdalin	Gentiobiose	*Prunus* spp.

These two cyanogenic glycosides are hydrolyzed to cyanohydrins, which undergo nonenzymatic conversion to hydrogen cyanide via hydrolysis by linamarinase.[4] Processing (e.g., sun drying, soaking, and boiling) removes about 80–95% of the cyanogenic compounds present in traditional African foods (gari, lafun, fufu) derived from the cassava root.[14] Disruption of the root tissue releases an endogenous enzyme, linamarinase, which hydrolyses linamarin to acetone cyanohydrins in the presence of high moisture content and low temperatures. After the formation of cyanohydrins, heat and low moisture content facilitate the spontaneous conversion of cyanohydrins to volatile hydrogen cyanide.[15] Inefficient processing of cassava root results in the persistence of cyanohydrins in the cassava meal. The storage of cassava in a deep freeze for 4 months after the slicing of the cassava in a food processor resulted in the hydrolysis of almost all of the linamarin in the cassava, whereas much smaller amounts of linamarin were lost during storage under the same conditions when the cassava was cut into 20-g slices.[16] Storage of gari or eba for 4 weeks at room temperature resulted in the loss of about one-half of the original linamarin content of roasted cassava that was fermented for at least 4 days prior to storage.[17]

Cycad Seeds

Cycad seeds contain the cyanogenic glycosides, cycasin and neocycasin. Cycasin and neocycasin A, B, C, and E (methylazoxymethanol β-D-glycoside) are unique toxins present in cycad species. These azoxyglucosides are glycosides of the same aglycone, methylazoxymethanol.[18] Cyanide production results from the hydrolysis of the glycoside to D-glucose and hydroxynitrile by the enzyme β-glycosidase. Hydroxynitrile forms hydrogen cyanide and the corresponding aldehyde or ketone following either spontaneous hydrolysis or catalytic conversion by hydroxynitrile lyase. However, the liberation of cyanide from this process is a minor pathway compared to the formation of nitrogen gas, formaldehyde, and methanol. Food processing removes some of the cyanide by inactivation of β-glycosidase or removal of the cyanogenic glycosides by exposure to β-glycosidases.

Poisonous Parts

The lima bean (*Phaseolus lunatus* L.) contains low concentrations of cyanogenic glycosides, and clinical toxicity in humans following the ingestion of these fruits is not well documented.[19] A sample of dry, mature, raw lima beans contained a cyanide content of about 38 mg/g that decreased to nondetectable concentrations after autoclaving or toasting for 20 minutes, as measured by colorimetry after acid hydrolysis.[20] The total amount of cyanide-containing compounds is substantially higher in young leaves than in older leaves. In an experimental study, the cyanogenic potential (i.e., total amount of cyanide-containing compounds), ranged from 0.7 μmol HCN/g leaf fresh weight in mature leaves of one strain of lima beans to 82.0 μmol HCN/g leaf fresh weight in young leaves of another strain.[21]

Sorghum (e.g., *Sorghum bicolor* L.) contains the cyanogenic glucoside, dhurrin, which releases hydrogen cyanide as a result of the activity of the heterotetrameric enzyme, hydroxynitrile lyase.[22] Flaxseed is an oilseed that contains about 35–45% oil along with cyanogenic glycosides, primarily linustatin and neolinustatin.[23] Flaxseed is a desirable food product because of the high content of α-linolenic acid and dietary fiber. The cyanide content of 10 cultivars of flaxseed ranged from 124–196 μg/g, as analyzed by high performance liquid chromatography with electrochemical detection.[24] Boiling water or solvent extraction removes 90–100% of the HCN content of flaxseeds.[25] The highest cyanogenic glucoside concentrations occur in extracted flaxseed mucilage, but baking muffins with flaxseed flour (i.e., 150 g flaxseed/kg) at 230°C (446°F) for 15–18 minutes eliminates the cyanogenic glucosides.[26] These compounds also are not detectable in processed flaxseed oil.

Fruit Kernels

Apricot, peach, and apple kernels as well as the stems, leaves, and roots of many species from the rose (Rosaceae) family contain cyanogenic glycosides, such as amygdalin. In a review of several studies on the HCN content of fruit kernels, the approximate amount of HCN releases were as follows: apricot, <0.05–4 mg/g; peach, 0.4–2.6 mg/g; and apple, 0.6 mg/g.[10] The cyanide content of apricot kernels (*Prunus armeniaca*) varies widely depending on a variety of poorly defined factors including cultivation practices, variety, and moisture content.[27] In several studies, the cyanide content of apricot kernels ranged from <0.05 mg/g to about 4 mg/g material compared with about 56 mg HCN/g amygdalin.[28,29] A study of pulverized apricot kernels demonstrated average cyanide yields of approximately 3 mg/g ground kernels, as measured by a simple colorimetric method.[30] In general, the hydrogen cyanide content is lower in peach kernels than in bitter almond or apricot kernels. Analysis of two peach kernels in one study demonstrated an average hydrogen cyanide content of approximately 0.45 mg/g of material as measured by a colorimetric method.[31] In another study, the hydrogen cyanide content of peach and apricot kernels was 2.6 mg/g and 2.92 mg/g, respectively, compared with 55.9 mg HCN/g amygdalin.[10] Various factors account for some the differences in cyanide content of peach kernels between these studies including variety, moisture content, physical properties used for analytical methods (e.g., chromatography or spectroscopy), and expression of results (e.g., HCN or glycoside). The cyanide content of apple (*Malus domestica*) seeds is low (0.6 mg/g) compared with bitter almond and apricot kernels, and toxicity from the ingestion of these seeds is unusual.[10]

Cassava

Cassava root typically contains <100 mg HCN equivalent/kg wet weight, but some "bitter" cultivars contain up to 500 mg HCN equivalent/kg wet weight. However, the amount of cyanide in foods (e.g., gari) derived from the cassava root depends on the processing methods.[32] All parts of the cassava plant contain cyanogenic glycosides with cyanogen content in tubers varying substantially (e.g., 15–400 mg HCN equivalent/kg fresh weight).[14] The main cyanogen in cassava is linamarin (i.e., >90%) with minor amounts of the closely related compound, lotaustralin.[16] Most cassava cultivars contain roots with cyanogenic glucoside content below 100 mg/kg wet weight, although some bitter cultivars may contain cyanogenic glycoside content up to 500 mg/kg wet weight.[2] Processing and fermenting of the cassava root for 5 days in water removes most (i.e., about 90%) of the cyano-

genic glycosides and converts the processed root to the storage form (e.g., gari). Studies of children eating meals from fried and boiled cassava root during normal times indicate that the exposure to cyanide from this food source is relatively low.[33] Acute intoxication from the ingestion of cassava root occurs primarily during periods of drought or intensive commercialization that results in inadequate processing of the cassava root.[34] The leaves and buds contain cyanogenic glycosides that may produce cyanide poisoning, especially if the leaves are boiled as tea. Intact cyanogenic plants do not release hydrogen cyanide because the substrates and the degrading enzymes occur in separate intracellular compartments.[2]

Mechanism of Toxicity

The release of hydrogen cyanide from cyanogenic precursors in certain plants is a constitutive plant defense against tissue disruption by herbivores. The effectiveness of this defense mechanism results primarily from the endogenous release of hydrogen cyanide within the gastrointestinal tract of the herbivore rather than the release of this gas during the feeding process.[35] The production of cyanide from cyanogenic plants depends both on the biosynthesis of cyanogenic glycosides and the coexistence of degrading enzymes localized in the apoplast. The generation of cyanide from cyanogenic glycosides is a two-step process involving deglycosilation and cleavage of the molecule. The latter process is regulated by β-glucosidase and α-hydroxynitrile lyase.[2] For example, the generation of cyanide from linamarin in cassava root involves the deglycosilation of linamarin by a β-glucosidase (linamarase) to acetone cyanohydrin, and the subsequent cleavage of acetone cyanohydrin to acetone and hydrocyanic acid by α-hydroxynitrile lyase. The latter reaction can occur spontaneously as a result of the instability of the cyanohydrin.

DOSE RESPONSE

Fruit Kernels

Ingestion of 20–40 apricot kernels by an adult female resulted in acute cyanide toxicity with disorientation that responded promptly to the administration of sodium nitrite and thiosulfate.[29] The chewing of approximately 30 apricot kernels by a 41-year-old woman produced generalized weakness, dyspnea, diaphoresis, and dysphagia within 20 minutes, which subsequently responded to intravenous sodium nitrite and sodium thiosulfate.[36] A man and a woman developed vomiting, headache, flushing, diaphoresis, and lightheadedness about 1 hour after consuming a milkshake containing 48 pulverized apricot kernels.[37] The symptoms rapidly resolved without sequelae.

Cassava

Experimental studies indicate that the consumption of cassava does not usually cause a significant increase in cyanide exposure. In a study of nonsmoking subjects, the ingestion of 1–4 kg fresh boiled cassava over 2 days did not produce a significant increase in urinary thiocyanate concentrations.[38] In an experimental study, volunteers ingested a meal of gari containing cyanohydrin equivalent to 128 µmol of cyanide.[39] Analysis of plasma from these volunteers demonstrated small amounts of cyanide that suggests that cyanide may accumulate in plasma following chronic ingestion of cassava.

TOXICOKINETICS

Absorption/Distribution

There are few data on the toxicokinetics of amygdalin or prunasin in humans. Limited animal studies suggest that the gastrointestinal tract poorly absorbs (i.e., <3%) oral doses of amygdalin, whereas the oral bioavailability of prunasin is about 50%.[40] In animal models, the occurrence of peak whole blood cyanide concentrations after oral administration of amygdalin and linamarin depends on the rate of enzymatic hydrolysis. A study of female golden Syrian hamsters indicated that peak whole blood cyanide concentrations following the oral administration of amygdalin and linamarin occurred 1 hour and 3 hours, respectively, after administration.[41] The protein binding of amygdalin is minimal.

Biotransformation/Elimination

The biotransformation of cyanogenic glycosides begins with the cleavage of the carbohydrate moiety by one or more β-glycosidases that form α-hydroxynitrile. Depending on the plant species, there are two distinct pathways that involve 1) the hydrolysis of cyanogenic disaccharides by the stepwise removal of the sugar residues, and 2) hydrolysis of the aglycone-disaccharide bond producing mandelonitrile and the corresponding disaccharides.[42] Figure 5.1 demonstrates these two pathways. Hydrolysis of amygdalin produces the active metabolite, prunasin (D-mandelonitrile-β-D-glucoside). Animal studies indicate that the elimination of amygdalin is rapid with most of the absorbed dose (62–96%) excreted in the urine during the first 24 hours after ingestion as unchanged drug.[43,44] The hepatic excretion of amygdalin is relatively small compared with renal excretion.[45] Following intravenous administration of 500 mg amygdalin

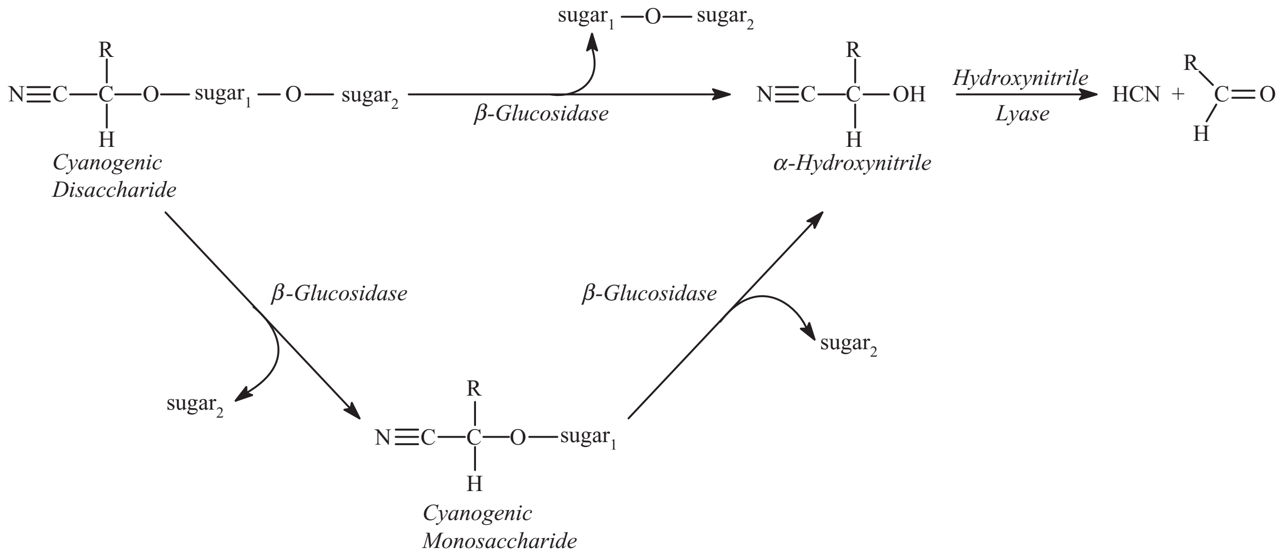

FIGURE 5.1. Biotransformation pathways of cyanogenic disaccharides. From Poulton JE. Localization and catabolism of cyanogenic glycosides. Ciba Found Symp 1988;140:69. Copyright John Wiley & Sons Limited. Reprinted with permission.

to cancer patients, the mean elimination half-life of amygdalin was approximately 2 hours with a mean plasma clearance of about 100 mL/min.[46]

Frequent intake of cassava root-derived foods (e.g., gari) substantially increases the plasma concentrations of thiocyanate, the major metabolic product of cyanide, despite the low concentrations of cyanide in the processed foods. Limited pharmacokinetic data indicate that approximately one-half of the linamarin is converted to cyanide and subsequently to thiocyanate following ingestion of linamarin-containing foods.[47] About one-fourth of the ingested linamarin appears in the urine unchanged, and the rest of the linamarin is metabolized to other compounds. The rise in the plasma cyanide concentration following ingestion of a single meal of well-processed cassava root is small (i.e., doubling of baseline concentrations) with a return to baseline plasma cyanide concentrations averaging about 7 ± 2 hours.[39]

CLINICAL RESPONSE

Acute

The clinical features associated with the ingestion of cyanogenic glycosides mimics cyanide poisoning, and the severity of the intoxication correlates to the dose of active cyanogenic compounds. The onset of vomiting, abdominal pain, weakness, dyspnea, diaphoresis, and lightheadedness followed by convulsions, stupor, disorientation, hypotension, metabolic acidosis, coma, respiratory failure, and cardiovascular collapse develops after exposure to high doses of cyanogenic glycoside-containing foods[48,49] or from the ingestion of laetrile.[50,51] Symptoms typically start within one half hour after consumption and progress quickly. A case series associated the ingestion of wild apricot seed ingestions by Turkish children with the sudden onset of vomiting and crying followed by fainting, lethargy, and coma.[52]

In a retrospective review of charts from 21 patients, the ingestion of cooked cycad seeds was associated with severe vomiting.[18] Other symptoms present in less than one-half of these patients included abdominal pain, headache, dizziness, weakness, tachycardia, and diarrhea. All patients tested for blood cyanide concentrations had elevated blood cyanide concentrations, but the blood cyanide concentrations were below values (0.5–1 mg/L) associated with serious toxicity. All symptoms resolved within 24 hours. Although case reports associated the ingestion of seeds and other plant material from *Cycas* species with fatalities,[53] forensic analysis of these cases did not include documentation of cyanide exposure. The ingestion of yam beans [*Pachyrhizus erosus* (L.)Urb.] causes an acute intoxication similar to cyanide poisoning including metabolic acidosis, nausea, vomiting, perioral paresthesias, and coma.[54] However, this bean contains rotenone rather than cyanide. Rotenone blocks nicotinamide adenine dinucleotide CoQ reductase (complex I) in the first step of mitochondrial electron transport.[55]

Chronic

Tropical Ataxic Polyneuropathy

Tropical ataxic polyneuropathy is a sporadic and endemic disease that causes gait ataxia, sensory poly-

neuropathy, optic atrophy, and neurosensory deafness. This disease is uncommon in patients under 40 years of age, and women are affected more often than men.[56] The endemic form occurs primarily in communities in southwestern Nigeria. Epidemiological studies in the 1950s and 1960s associated this disease with the high intake of cassava.[57] Although recent studies confirm the relatively high consumption of cassava foods in Nigerian communities with endemic ataxic polyneuropathy,[58] consumption of large quantities of cassava occurs in Nigerian communities without this disease.[59] A nested case-control study of cases of endemic ataxic polyneuropathy did not detect a significant difference in the intake of cassava or the plasma thiocyanate concentrations between cases and controls.[60]

Konzo

Konzo (i.e., "tired legs") is a permanent spastic upper motor neuron disorder occurring in rural areas of Mozambique, Tanzania, Central African Republic, Cameroon, and the Democratic Republic of Congo. The abrupt onset of this spastic paraparesis or tetraparesis is associated with the consumption of cassava, particularly in children and women of childbearing age with low protein intake (i.e., low sulfur amino acids).[61] About one-half of patients with konzo also have an optic neuropathy manifest by decreased visual acuity, alteration of the visual fields, and/or pallor of the optic disk.[62] The most common eye complaint in patients with konzo is transient blurred vision that is not usually associated with progressive loss of vision. In contrast to optic effects (i.e., amblyopia) associated with tropical ataxic polyneuropathy, visual field defects and pallor of the optic disks are the most common eye abnormalities associated with konzo.[63] Visual evoked potentials are abnormal in approximately half of the patients with konzo, manifest by delayed latency and reduced amplitudes. A small number of patients have pendular nystagmus consisting of involuntary, lateral, and medial eye movements with equal velocity in both directions. The severity of the ophthalmological complaints does not correlate to the severity of spastic paresis.[62] The differential diagnosis includes epidemic optic neuropathy in Tanzania, Nigeria, and Cuba, tobacco amblyopia, Leber's hereditary optic neuropathy, and vitamin B deficiency (e.g., thiamine, cobalamin).

Western Pacific Amyotrophic Lateral Sclerosis/Parkinsonism-Dementia Complex

Western Pacific amyotrophic lateral sclerosis/parkinsonism-dementia complex (WP ALS-PD) is a prototypic neurodegenerative disorder with symptoms similar to amyotrophic lateral sclerosis, Parkinson's disease, and Alzheimer's disease. The incidence of this neurodegenerative disease is 50–100 times more common in the Chamorro people of Guam than other Pacific populations.[64] The nonprotein amino acid β-methylamino-L-alanine (BMAA) in the Guam ecosystem is the most likely neurotoxic compound rather than a cyanogenic compound.

Hypersensitivity

Food allergies may develop following the consumption of the skin of certain fruits (apricot, plum, cherry, peach), particularly in patients with allergic rhinitis.[65]

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect amygdalin include thin layer chromatography (TLC), high performance liquid chromatography (HPLC), and gas chromatography mass spectrometry (GC/MS).[66] Amygdalin and prunasin are quantifiable in biological samples (urine, plasma) by HPLC on a reversed phase column with detection at 215 nm and confirmation by mass spectrometry.[67] Methods for detecting hydrogen cyanide in biological samples include spectrometry, electrochemical analysis with cyanide ion-selective electrode, GC, GC/MS, and HPLC/MS.[68,69] The latter two methods are widely used methods for the quantitation of cyanide after headspace extraction or derivatization. More recent and rapid methods of detecting cyanide in biological specimens include capillary gas chromatography with cryogenic oven trapping (limit of detection [LOD]: 2 ng/mL),[70] capillary electrophoresis with fluorescence detection (LOD 0.1 ng/mL),[71] automated headspace GC (LOD: 13.8 μg/L),[72] and isotope-dilution GC-MS (LOD: 0.003-0.007 μg/g).[73]

Biomarkers

There are few data correlating blood cyanide concentrations to the ingestion of specific amounts of cyanogenic plants. In the presence of a compatible history, the presence of elevated blood cyanide concentrations confirms exposure to cyanogenic plants, but the results are not usually available to guide clinical management.

Abnormalities

Cyanide poisoning inevitably produces a metabolic acidosis that results in an increased serum lactate concentration from anaerobic metabolism.[74] The lack of metabolic acidosis in a symptomatic patient suggests a diagnosis other than cyanide poisoning.

TREATMENT

Treatment of poisoning from exposure to cyanogenic plants is similar to the treatment of cyanide poisoning. Decontamination measures are not usually necessary because of the limited absorptive capacity of activated charcoal to cyanide. Mild to moderate ingestions usually require only supportive care. Indications for the use of an antidote (nitrites/thiosulfate or hydroxocobalamin) include alteration in mental status, severe acidosis, continuous seizures, and refractory hypotension. The administration of the cyanide antidote kit to children requires the appropriate adjustments for weight and hemoglobin content to avoid methemoglobinemia. Clinical features that suggest an appropriate response to nitrites and thiosulfate or hydroxocobalamin include the following: normalization of vital signs (blood pressure, pulse), normal mentation, cessation of seizure activity, spontaneous respirations, and resolution of metabolic acidosis.[75] The presence of persistent metabolic acidosis may require a continuous infusion of sodium thiosulfate (2 g/h) for 24 hours.[36] Survival has occurred in patients with cyanide poisoning including laetrile-induced, severe cyanide intoxication (coma, metabolic acidosis, profound hypotension requiring aggressive support with vasopressors) following only supportive care.[76]

Chapter 6

CYCAD SEEDS and CHRONIC NEUROLOGIC DISEASE
(*Cycas* Species)

HISTORY

Neurodegenerative diseases are disorders of the central nervous system that result from the selective and premature atrophy of functionally related neurons without obvious causes, such as slow viruses. The most prevalent neurodegenerative human diseases are Alzheimer's dementia (AD), Parkinson's disease, and amyotrophic lateral sclerosis (ALS). Between 1942 and 1944, the Japanese Army occupied Guam, and the Chamorros (indigenous peoples of Guam) relied primarily on cycad as one of the few available food sources. In the 1950s, the occurrence of ALS in the Chamorro people in the Mariana Islands (Guam, Rota) markedly exceeded the prevalence of this disease in the United States and other developed countries. Further investigations revealed that other neurodegenerative diseases (Alzheimer's-like dementia, Parkinson's disease) also exceeded the prevalence of these diseases in developed countries. The term, Western Pacific amyotrophic lateral sclerosis-parkinsonism-dementia complex (WP ALS-PD), was applied to this set of neurodegenerative diseases. Excess rates of this disease were also found in the Auyu and Jakai people of West New Guinea and Japanese residents of the Kii Peninsula (Honshu Island).[1,2] A prospective, follow-up study of 899 Chamorros in the Mariana Islands detected 23 new cases of parkinsonism-dementia and 5 new cases of ALS between 1968 and 1983.[3] Of 23 variables selected during baseline examinations in 1968, only the preference for traditional Chamorro food was significantly associated with an increased risk of parkinsonism-dementia. The decline of WP ALS-PD after World War II along with the absence of recognizable transmissible or heritable factors resulted in a search for neurotoxins in traditional foods (e.g., cycad flour) and medicines. Early studies suggested that β-*N*-methylamino-L-alanine (L-BMAA), an amino acid present in food sources derived from the seeds of the cycad tree (*Cycas circinalis*), was a potential slow neurotoxin.[4] This compound is a *N*-methyl-D-aspartate (NMDA)-receptor agonist at high concentrations and a non-NMDA-receptor agonist at low concentrations that is structurally related to, but much less potent than the neurotoxin associated with lathyrism (β-*N*-oxalyl-amino-L-alanine).[5] However, experimental models using L-BMAA have not reproduced WP ALS-PD, and the consumption of large amounts of processed (i.e., washed, fermented) cycad seeds does not necessarily produce the disease.[6] Although the incidence of neurodegenerative disease has declined and the median age of onset has increased since the 1950s along with a reduction in the consumption of cycad seeds, neurodegenerative diseases continue to significantly impact the health of the Chamorro people of Guam.[7]

BOTANICAL DESCRIPTION

The Cycadaceae (cycad) family contains about 45 primitive species of seed-bearing plants that probably dominated the world's vegetation during the Jurassic and early Cretaceous periods.[8] Although the cycad tree has fronds and an appearance similar to the sago palm

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

(*Metroxylon sagu* Rottb.) from the Arecaceae (palm) family, the cycad tree (*Cycas circinalis* L.) is not a true palm like the true sago palm. Because the cycad tree has fronds, a popular term for this tree is the false sago palm. The genus, *Cycas*, contains other species including *C. revoluta* Thunb. (sago palm) and C. *rumphii* (Queen sago).

Common Name: Cycad tree, false sago palm, queen sago

Scientific Name: *Cycas circinalis* L.

Botanical Family: Cycadaceae

Physical Description: A perennial evergreen, tree-like herb with pinnate foliage and pollen cones. The mature seeds are pale reddish yellow.

Distribution and Ecology: Species in the genus are widely distributed throughout the world from Madagascar and the east coast of Africa to northern Australia, the Mariana Islands, and southern Japan. In southern Florida, the Gulf Coast, and warm sections of California, *C. revoluta* and *C. circinalis* are used as ornamental plants.

Common Name: Sago palm, king sago palm, cycad, bread tree (Africa)

Scientific Name: *Cycas revoluta* Thunb.

Botanical Family: Cycadaceae

Physical Description: A slow growing fern-like tree that reaches up to 3 m (10 ft), usually as a thick, shaggy, solitary trunk topped by a terminal crown of stiff, deep glossy green, feathery palm-like pinnate fronds 1–2 m (3–7 ft) long. The shiny leaflets are tipped with spines and curved at the margins. The brown, petal-less flowers are clustered together, and form an orange fruit.

Distribution and Ecology: This cycad species is a native of Southern Japan, but has been naturalized throughout temperate and tropical habitats including Taiwan.

Common Name: Queen sago

Scientific Name: *Cycas rumphii* Miq.

Physical Description: The bright green, glossy leaves are about the same size as *C. circinalis* with 150–200 leaflets. The fusiform pollen cones are yellow to pale brown. The flatten-ovoid seed are 45 mm (2 in.) long with a spongy endocarp present.

Distribution and Ecology: This plant is a native species of Indonesia that inhabits closed woodlands or forests near shorelines in S. Borneo, N.E. Java, Maluku Papua, and Sulawesi. Figure 6.1 displays a female specimen of *C. rumphii* with seeds on the edges of the leaves.

FIGURE 6.1. Female specimen of *Cycas rumphii.* Miq. © 2005 Rune Midtgaard. See color insert.

EXPOSURE

In traditional Chinese medicine, the seeds of *Cycas revoluta* are used as treatments for gastrointestinal disturbances, musculoskeletal pain, cough, and hypertension.

PRINCIPAL TOXINS

Unwashed cycad flour contains cycasin (methylazoxymethanol *beta*-D-glucoside), an amino sugar with a toxic aglycone called MAM (methylazoxymethanol). This compound is unique to the cycad family, and cycasin is a weak cyanogen compound (pseudocyanogen). In a study of 17 samples of traditionally processed cycad flours obtained from Chamorro residents of Guam and the adjacent island of Rota, the content of β-*N*-methylamino-L-alanine (BMAA) and methylazoxymethanol *beta*-D-glucoside (cycasin) ranged from nondetectable to 18.39 µg/g (M = 5.44 ± 1.56 µg/g) and 0.004–75.93 µg/g (M = 12.45 ± 5.0 µg/g), respectively, as measured by high performance liquid chromatography (HPLC).[9] Animal tests suggest that MAM is a hepatic carcinogen and animal teratogen, but neuropathology in animals does not correlate to the abnormalities associated with the WP ALS-PD complex.[10,11] Washing, boiling, fermenting, and storage of cycad flour removes substan-

tial amounts of toxins (cycasin, MAM, L-BMAA) as well as β-glycosidase enzymes.[12] Unwashed cycad flour also contains the neurotoxin, β-methylamino-L-alanine (L-BMAA), which is a *N*-methyl-D-aspartate (NMDA) agonist that produces neurodegeneration following some routes of administration. However, washing of cycad flour substantially reduces the L-BMAA content, and the residual amount (0.005%) of L-BMAA after washing may not be sufficient to cause neurodegenerative disease.[13] In animal studies, L-BMAA is substantially less neurotoxic than the structurally related excitatory plant amino acid, β-*N*-oxalylamino L-alanine (L-BOAA), which is associated with lathyrism.[14] Animal studies suggest that another neurotoxin (e.g., β-sitosterol-β-D-glucoside) or a toxic metabolite is a causal factor in WP ALS-PD complex.[15,16] Other nonprotein amino acids present in cycad flour include β-alanine, α-aminoadipic acid, γ-aminobutyric acid, and pyroglutamic acid.[17]

DOSE RESPONSE

The ingestion of 1–30 seeds from *C. revoluta* was associated with severe gastrointestinal distress and other nonspecific symptoms that resolved within 24 hours.[18] These patients did not develop clinically significant respiratory depression or hypotension.

TOXICOKINETICS

Cycasin is a pseudocyanogenic compound that releases minor amounts of hydrogen cyanide following the hydrolysis of cycasin by bacterial β-glycosidases in the alkaline environment of the small intestines. Most of the aglycone (methylazoxymethanol) formed by this reaction is degraded to nitrogen gas, methanol, and formaldehyde, particularly in the acidic conditions of the stomach. In contrast to cycasin, the unstable cyanohydrin (α-hydroxynitrile) formed from cyanogenic compounds (amygdalin, prunasin) releases substantial amounts of hydrogen cyanide following hydrolysis of these compounds.

CLINICAL RESPONSE

In domestic animals and humans, ingestion of cycad seeds causes the following two distinct syndromes: 1) an acute gastrointestinal illness sometimes involving the liver, and 2) a chronic neurological disorder characterized by ataxia.

Acute

The ingestion of improperly or unprocessed cycad seeds can cause severe gastrointestinal distress manifest by nausea, vomiting, diarrhea, headache, and lightheadedness. Although historical accounts suggest that the acute ingestion of cycad seeds can cause loss of consciousness, hepatitis, and death,[19] the role of cycad seeds in the development of these serious complications is unclear because of the lack of direct evaluation of the affected patients. In a retrospective chart review conducted at the Poison Control Center in Taiwan, 21 cases of cycad seed poisoning were identified.[18] Severe vomiting was the most prominent symptom with a mean onset about 3 hours after ingestion of the cycad seeds. Other symptoms included abdominal pain, headache, dizziness, weakness, tachycardia, diarrhea, and hypertension. Although blood cyanide and thiocyanate concentrations were elevated in the 6 patients tested, these concentrations did not reach toxic concentrations.

Chronic

WP ALS-PD complex is a chronic neurodegenerative disease prevalent in small populations in the Mariana Islands, West New Guinea, and the Japanese island of Honshu. The onset of the disease and the progression of the disease are variable with both rapid and slow (i.e., years to decades) onset after exposure to suspected causal factors (cycad seeds).[20] Characteristics of ALS include progressive weakness of the extremities, spasticity, fasciculations, muscle atrophy, and bulbar dysfunction. The parkinsonism-dementia complex includes bradykinesia, resting tremor, decreased blink reflex, loss of fine motor movements, muscle rigidity, dysphagia, dysarthria, incontinence, upper- and lower-motor neurologic signs with progression to flexion-contractures, and progressive dementia. Pathological changes involve the presence of neurofibrillary tangles in association with prominent degeneration of the neurons in the upper and lower motor neurons, hippocampus, substantia nigra, and medial basal forebrain.[21]

The suspected link is the presence of symbiotic, free-living cyanobacteria in the coralloid roots of cycad trees that produce BMAA. BMAA is concentrated in the cycad seeds and also in flying foxes (*Pteropus mariannus* Desmarest) that forage on these seeds.[22] Flying foxes are a delicacy for the indigenous Chamorro people, who eat the fox after boiling the whole fox in coconut cream. A case-control study of patients with dementia, mild cognitive impairment, or parkinsonism-dementia complex on Guam demonstrated an increased risk for patients exposed to traditional cycad-derived food (fadang), particularly for men.[23] The adjusted odds ratio for eating fadang in young adulthood was 2.87 (95% CI: 1.48–5.56). Although constituents in unprocessed flour are carcinogenic in long term animal studies,[24] there are inadequate animal and human data to indicate that the

consumption of processed cycad flour increases the incidence of cancer.[25]

DIAGNOSTIC TESTING

Analytical methods to detect the presence of BMAA in plant and animal tissue in the subpicomole range include gas chromatography mass spectrometry (GC/MS)[17] and reversed phase HPLC method with precolumn derivatization by 9-fluorenylmethyl chloroformate.[26] Based on an electrophysiology study of 29 Chamorro patients with neurodegenerative diseases, a peripheral neuropathy can occur in these patients. Three patients with parkinsonism-dementia out of 16 patients with neurodegenerative disease had mild reduction in central nerve conduction manifest by mildly abnormal tibial somatosensory evoked potentials (SEPs).[27]

TREATMENT

Treatment is supportive. Acute ingestion of unprocessed cycad seeds produces gastroenteritis, and patients should be evaluated for fluid and electrolyte balance depending on the severity of symptoms. Decontamination measures are unnecessary.

Chapter 7

DJENKOL BEAN
[*Archidendron jiringa* (Jack) I. C. Nielsen]

BOTANICAL DESCRIPTION

Common Name: Djenkol tree (Indonesia), krakos (Cambodia), jering (Malaysia), niang-yai (Thailand), jenkol, genkol, yiniking, yi-ring, ma-niang, cha-niang, niang, kra-niang

Scientific Name: *Archidendron jiringa* (Jack) I. C. Nielsen [*Abarema jiringa* Kosterm, *Albizzia jiringa* (Jack) Kurz, *Inga jiringa* (Jack) Jack, *Mimosa jiringa* Jack, *Pithecellobium jiringa* (Jack) Prain, *Pithecellobium lobatum* Benth., *Zygia jiringa* (Jack) Kosterm]

Botanical Family: Mimosaceae (Mimosa)

Physical Description: The djenkol bean has a broad, round shape and reddish color. The beans grow in large, dark purple pods (3–9 beans/pod) on the djenkol tree, which grows to 25 m (82 ft) in height. These beans resemble a large, flattened horse chestnut, and the crushed bean emits a faint sulfurous odor.

EXPOSURE

Djenkol beans are a local delicacy in Indonesia, Malaysia, southern Thailand, and Myanmar. The beans are commercially available in markets during most of the year and are consumed raw, roasted, or fried.

PRINCIPAL TOXINS

Chemical Composition

The djenkol bean contains the sulfur-containing amino acid, djenkol acid (CAS RN: 498-59-9, $C_{11}H_{23}N_3S_3O_6$) in the range of about 0.3–1.3 g/100 g wet weight.[1] This compound is a cysteine thioacetal of formaldehyde as displayed in Figure 7.1.

Physiochemical Properties

Boiling, frying, or roasting the djenkol bean does not necessarily prevent toxicity as a case report temporally associated the development of acute renal failure with the ingestion of fried djenkol beans.[2] Typically, the ingestion of djenkol beans produces a pungent smell in the breath and urine of affected individuals.[3]

Mechanism of Toxicity

The mechanism of renal failure has not been clearly established. Animal studies demonstrate variable amounts of acute tubular necrosis with occasional glomerular involvement after the oral administration of djenkolic acid extracted from djenkol beans with 70% ethanol and water.[1] The peak incidence of djenkolism

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

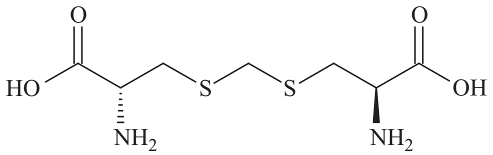

FIGURE 7.1. Chemical structure of djenkol acid.

occurs in the rainy season (September–January) corresponding to the bloom time of the djenkol tree.[4]

DOSE RESPONSE

Most people eat djenkol beans without ill effects, and there is no clear dose-response effect for the development of djenkolism. Although the occurrence of renal failure is frequently associated with the consumption of raw beans with low fluid intake,[5] the development of djenkolism does not depend on the method of preparation or the age of the fruit. The dose of djenkol beans associated with acute renal failure is highly variable (1–20 beans).[6] The development of djenkol bean poisoning can occur after numerous symptom-free meals of djenkol beans, and the attack rate can be low in large families consuming similar amounts of djenkol beans. Prior poisoning with djenkol beans does not confer immunity or hypersensitivity to subsequent meals of djenkol beans.

TOXICOKINETICS

There are inadequate data to determine the toxicokinetics of djenkol acid in humans.

CLINICAL RESPONSE

Acute Effects

The clinical features of djenkolism range from asymptomatic hematuria, dysuria, and abdominal pain to gross hematuria, severe flank pain, and acute renal failure. Mild djenkolism develops within 2–12 hours after ingesting djenkol beans, manifest by hypogastric cramps, flank pain, vomiting, diarrhea, dysuria, hematuria, and opaque ("milky") urine. Case reports associate acute djenkolism with the development of acute renal failure, manifest by nausea, vomiting, bilateral flank pain, gross hematuria, hypertension, and transient oliguria.[2,7] Phase-contrast microscopy of urinary sediment and renal biopsy reported in this case report was consistent with acute tubular necrosis rather than glomerular disease. There was no evidence of ureteral obstruction. Symptoms usually resolve within 3 days with supportive care.[6]

Rare case reports associate the consumption of djenkol beans with the development of urethral stones, obstruction of the ureters, and urinary retention.[8]

Chronic Effects

In a study of 609 school children aged 7–11 years in an urban area of Thailand, 78% of the children had a history of djenkol bean consumption with 38% ingesting these beans within 24 hours of the interview.[9] The presence of hematuria was about 4-fold (crude odds ratio = 3.7) higher in children with a history of djenkol bean consumption compared with children not consuming djenkol beans. There was no significant difference in the presence of crystalluria or pyuria between these two groups.

DIAGNOSTIC TESTING

Urinary abnormalities in cases of renal failure associated with the ingestion of djenkol beans include hematuria, proteinuria, and needlelike crystals of djenkolic acid. Crystals of djenkol acid are usually, but not always, present in the urine of patients with djenkolism. Persistent or recurrent microscopic hematuria in children consuming djenkol beans is not usually associated with clinical effects, but there are few data on the long- term effects of hematuria secondary to chronic djenkol bean consumption.[9] Renal biopsies of patients with djenkolism typically demonstrate evidence of acute tubular necrosis with little interstitial nephritis, ureteral obstruction, or glomerular lesions.[2]

TREATMENT

Treatment is supportive with careful monitoring of renal function. Generous fluid intake and alkalinization potentially increase the dissolution of djenkol crystals (pK_a = 5.1), although there are few clinical data to confirm the efficacy of this treatment. Decontamination measures are unnecessary. Most patients recover without sequelae.

Chapter 8

GRASS PEA and NEUROLATHYRISM
(*Lathyrus sativus* L.)

HISTORY

Carbonized fossils indicate that the grass pea was domesticated in the Near East, and then cultivated with cereals in the Balkans since the Neolithic period.[1] Human lathyrism is a spastic lower-extremity paraplegia that has been associated with the ingestion of grass peas since the time of Hippocrates.[2] The Duke of Wurttenberg prohibited the baking and consumption of bread containing grass peas in Germany during the late 17th century.[3] In 1873, Cantani identified this neurological disease as lathyrism.[4] Epidemics of neurolathyrism usually occur during times of food shortages, such as drought, flooding, or wars.[5,6] Epidemics of neurolathyrism occurred during the Spanish Civil War (1936–1939), in China, Bangladesh, and India during the 1970s, and in Ethiopia during the 1970s and 1990s.[7]

BOTANICAL DESCRIPTION

Although *Lathyrus sativus* is the species commonly associated with neurolathyrism, other *Lathyrus* species also contain neurotoxins including *Lathyrus cicera* L. (red pea) and *Lathyrus clymenum* L. There are more than 100 *Lathyrus* species in the United States. The chick pea (*Cicer arietinum* L.) is a nontoxic legume that does not produce neurolathyrism following chronic consumption.

Common Name: Grass pea, white pea, chickling pea, vetchling, khasari (India), guaya (Ethiopia), shan li dou (China), pois carrè (France)

Scientific Name: *Lathyrus sativus* L.

Botanical Family: *Fabaceae* (pea)

Physical Description: A perennial vine that grows up to 1 m (about 3 ft) in length. The pinnately compound leaves usually have two, small linear-lanceolate leaflets with the upper leaflets being tendrils.

Distribution and Ecology: *Lathyrus sativus* is a vine introduced into the United States from Europe with distribution limited to Minnesota, California, Oregon, Maryland, and Massachusetts. This legume grows as a weed in cultivated land, particularly in moist areas with full sun. However, this plant is relatively drought tolerant and widely cultivated in Central, South, and East Europe, the Mediterranean, Southeast Asia, and Africa.

EXPOSURE

The grass pea is an inexpensive, drought-tolerant food staple for parts of Africa (e.g., Ethiopia) and Asia (e.g., Bangladesh, India, and Nepal) that are susceptible to drought. Advantageous characteristics of grass pea include tolerance to extreme water and poor soil conditions, resistance to pests, high protein content in seeds, and nitrogen fixation. Under normal conditions this substance is a small part of the diet, but during periods of food shortage the consumption of grass peas increases dramatically because of the ability of *Lathyrus sativus* to survive under harsh environmental conditions.[8] The Indian staple, ghotu, is prepared by cooking a mixture of grass pea and rice to form a stiff porridge. In Ethio-

pia, chapati and kitta are unleavened breads formed from grass pea seeds. The latter bread may contain high concentrations of neurotoxins.[9] This legume is used as flour in cattle feed.

PRINCIPAL TOXINS

Structure and Properties

The spastic paraparesis of neurolathyrism results from the ingestion of peas and foliage from drought-tolerant *Lathyrus sativus* that contain the neuroexcitatory amino acid, 3-*N*-oxalyl-L-2,3-diaminopropanoic acid (β-ODAP).[10] A synonym for β-ODAP is L-2-amino-3-oxalylaminopropanoic acid (β-oxalylaminoalanine). β-ODAP is a structural analog of glutamine.[11] The α-isomer represents only about 5% of the total quantity of ODAP, but heat and storage at neutral pH causes increased formation of α-ODAP.[12] Prolonged cooking decreases the amount of β-ODAP in grass pea seeds by converting this neurotoxin to the less toxic isomer, α-ODAP.[13] Animal studies indicate that the α-isomer possesses relatively low neurotoxicity compared with β-ODAP, and the conversion of β-ODAP to α-ODAP during food processing reduces the toxicity of chickling peas.[14] In addition to β-ODAP, the seedlings of *L. sativus* also contain other potential neurotoxins [e.g., α-amino-γ-(isoxazolin-5-on-2-yl)-butyric acid].[15] β-ODAP is water soluble, and boiling grass peas for 1 hour followed by decanting the water removes about 70% of the β-ODAP from the pea.[16]

Poisonous Parts

The average concentration of β-ODAP in ripe seeds from *L. sativus* is usually <1%, depending on the variety, season, and growing conditions.[8] The mean β-ODAP content in dry seeds purchased in an Ethiopian market was 0.74% wet weight as measured by flow injection assay.[17] In general, seedlings contain the highest concentrations of neurotoxins compared with ripe seeds.[18] Analysis of 3-day-old seedlings demonstrated β-ODAP concentrations ranging from 0.34–0.79 mg/g dry weight in low-toxin lines to 5.5–7.16 mg/g dry weight in wild types.[19] In a study of 63 samples of grass pea seeds used in food preparations at an Ethiopian village, the β-ODAP concentration ranged from 282–810 mg/100 g dry seeds with a mean of 455 mg/100 g.[9] The highest concentrations of β-ODAP occur in bread and roasted forms of grass pea foods, whereas boiled snacks and flour derived from grass pea seeds steeped in boiling water contained relatively low β-ODAP concentrations. Detoxification of grass pea seeds requires the removal of the husk and boiling of the dehusked seeds for several hours in hot water. The supernatant contains about 70–80% of the neurotoxin originally present in the grass pea seeds.[9] This water is discarded. The scarcity of water during a drought increases the risk that the grass pea seeds will not be properly detoxified. A simulated kitchen experiment suggested that steeping grass pea seeds in large volumes of water for 3 minutes along with the decanting of excess water removes approximately 30% of the β-ODAP content in the grass pea seeds.[9] Grass pea contains a 24 kDa allergenic protein, but the exact structure of this allergen has not been delineated.[20]

DOSE RESPONSE

The development of neurolathyrism depends on the daily dose of grass peas, the duration of consumption, climatic conditions, and physical condition. Generally, the development of neurolathyrism requires the ingestion of grass peas for 2–3 months as one-third to one-half of the total dietary intake.[2] Cases of neurolathyrism usually occur only during food-shortages because this disease does not appear when grass pea is a minor component of a varied diet.[13] The attack rate and severity of neurolathyrism is variable, even in the same family consuming similar diets. The daily consumption of rations consisting of 400 g of grass pea (*Lathyrus sativus*) boiled in water and 200 g baked bread (80% barley, 20% chopped straw) for 3 months was associated with various degrees of neurolathyrism in about 70% of Jewish prisoners in a German forced labor camp.[21] Ukrainian and Russian inmates survived on a diet of 200 g/day of grass peas for 3–6 months until the amount of grass peas increased to 400 g/day. Neurological signs develop in primates 3–10 months after the initiation of a grass pea diet containing 1.1–1.5 g/kg body weight.[22]

Mechanism of Toxicity

The human variety of lathyrism is a chronic neurologic disease called neurolathyrism that results from the excessive ingestion of the peas from *Lathyrus sativus*.[23] Duplication of this disease in animals is difficult. Animals fed peas from *Lathyrus* species containing β-aminopropionitrile develop skeletal deformities and aortic aneurysms rather than neurological disorders. This animal disease affects primarily collagen tissue and is called osteolathyrism. Neurolathyrism and the minor bone changes seen in humans probably result from the neurotoxin β–*N*–oxalylamino-L-alanine (L-3-oxalylamino-2-aminopropionic acid), which is structurally similar to the putative neurotransmitter glutamate.[24] Experimentally, this neurotoxin is a competitive agonist of the 3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)

subtype of the glutamate receptor.[22] These inotropic quisqualate receptors are one of the postsynaptic neuronal receptors that bind the putative excitatory neurotransmitter glutamate. Persistent depolarization causes failure of energy-dependent cellular homeostasis and neuronal death. Animal studies suggest that the neurotoxicity induced by L-β-ODAP is partially mediated by the activation of group I metabotropic glutamatergic receptors by indirect mechanisms.[25] Pathological changes in patients with neurolathyrism are usually mild. The prominent abnormalities involve the symmetrical axonal degeneration of crossed and uncrossed pyramidal tracts in the lumbar region along with mild degeneration of the spinocerebellar tracts.[26] Light microscopy typically demonstrates degeneration of the corticospinal pathways, (e.g., lateral pyramidal tracts) distal to the mid-thoracic level with preservation of anterior horn cells in the spinal cord.[21]

TOXICOKINETICS

The low incidence of neurolathyrism in humans after excessive consumption of the pulse, *Lathyrus sativus*, even under severe drought and famine conditions, suggests that humans usually metabolize the major neurotoxic amino acid (β-*N*-oxalyl-L-α,β-diaminopropionic acid or β-ODAP) to a nontoxic metabolite. In contrast to animal studies, the urinary excretion of unchanged β-ODAP in humans is low.[27] The difference in toxicokinetics may explain the low incidence of neurolathyrism in humans compared with susceptible animal species.

CLINICAL RESPONSE

Central Nervous System

The ingestion of parts including peas from the genus *Lathyrus* produces a progressive, chronic intoxication rather than acute toxicity. The disease is irreversible, but neurolathyrism rarely progresses after the cessation of further consumption of grass peas. The clinical pattern of neurolathyrism involves varying spasticity of the lower extremities along with relatively mild muscle weakness. The spasticity of the lower extremities causes neurological effects ranging from ataxic gait to contractures that prevent ambulation. Increased muscle tone in the legs (thigh extensors, thigh adductors, gastrocnemius) along with muscle weakness produce inversion of the feet and a lurching, cross-legged gait.[28] Evidence of a peripheral neuropathy does not usually occur unless the patient has severe neurolathyrism. Superficial sensation, rectal sphincter tone, cranial nerve function, upper extremity muscle tone, and mentation are usually normal. In a follow-up study of 800 concentration camp victims with neurolathyrism, the number of former prisoners with spastic paresis of the lower legs, upper and lower motor lesions, and peripheral neuropathies were 80%, 15%, and 5%, respectively.[21] During the acute stage of the disease, young men (10–20 years) were most affected.

Neurolathyrism is rare in well-nourished adults and postmenopausal women.[29] There are no well-defined, predisposing factors for the development of neurolathyrism. Other features of neurolathyrism include gastrointestinal distress, urinary frequency and urgency, sexual dysfunction, and neurasthenic symptoms (insomnia, thirst, short-term memory loss).[30]

Skeletal System

Abnormalities outside the nervous system are uncommon. Some skeletal bony abnormalities were reported, but these bony abnormalities probably resulted from secondary stresses produced by the neurologic lesions.[31] In a study of 500 patients with neurolathyrism in Bangladesh, 60 patients had skeletal abnormalities and arthralgias.[32] Examination of these 60 patients demonstrated the characteristic features of osteolathyrism (e.g., failure of fusion in vertebral and iliac epiphyses) in only 2 patients.

Hypersensitivity Reactions

Occasional case reports associate exposure to *Lathyrus sativus* flour with allergic responses including occupational asthma.[33] A 42-year-old man developed rhinorrhea, pruritus, tearing, wheezing, and dyspnea after occupational exposure to saw dust that contained flour from *L. sativa*.[34] He had a history of seasonal rhinitis and a family history of atopy. Skin prick testing and bronchial provocation tests were positive following exposure to *L. sativus* flour.

DIAGNOSTIC TESTING

Analytical Methods

Methods to quantitate β-ODAP in solid samples include spectrophotometry, reverse phase high performance liquid chromatography (RP/HPLC),[35] capillary zone electrophoresis,[36] and liquid chromatography with refractory index and bioelectrochemical detection.[37] The limit of detection for β-ODAP using the latter method was 2 μM. The use of precolumn derivatization with 1-fluoro-2,4-dinitrobenzene and RP/HPLC with UV detection (360 nm) allows the detection β-ODAP in the range of 10 pmol.[38]

Abnormalities

Electrophysiological changes associated with neurolathyrism are usually minor and nonspecific. In a study of eight former Wapniarka concentration camp prisoners with neurolathyrism, all nerve conduction studies including F-wave latencies were normal.[39] However, several of the patients had electromyographic evidence of α-motor neuron disease in the lumber spinal cord that may have resulted from chronic muscle denervation. In an electrophysiological study of 17 patients with endemic neurolathyrism (mean duration 15.6 years with a range of 2–30 years), 14 patients demonstrated slowing of the central motor conduction to the tibialis anterior muscle.[40] Slowing of peripheral motor nerve conduction of the upper extremity was present in only 4 patients.

TREATMENT

Management of grass pea ingestions involves supportive care. Decontamination is not usually necessary for ingestions by children.

Chapter 9

NUTMEG
(*Myristica fragrans* Houtt.)

HISTORY

Nutmeg probably was imported into Europe during the 12th century by Arab merchants. For many years, this spice has been used as an aromatic stimulant, abortifacient, antiflatulent and as a means to induce menses.[1] The Portuguese discovered the nutmeg tree on the Banda Islands of Indonesia (Spice Islands) in 1512. In 1576, de Lobel reported the first case of nutmeg intoxication in a pregnant English woman, who ingested 10–12 nutmeg nuts.[2] Beginning in the 17th century, the Dutch controlled the Spice Islands, and they monopolized the spice trade until the British obtained nutmeg seedlings from the Banda Islands at the end of the 18th century. References to the central nervous system effects of nutmeg appeared in the first part of the 19th century when Purkinje developed lethargy after consuming three nutmeg nuts.[1] Because of the alleged hallucinogenic and euphoria-inducing properties of nutmeg, abuse of this spice has occurred for many years, particularly in persons with limited access to other drugs. The autobiography of Malcolm X contains accounts of his use of nutmeg while incarcerated.[3]

BOTANICAL DESCRIPTION

Common Name: Nutmeg

Scientific Name: *Myristica fragrans* Houtt.

Botanical Family: Myristicaceae (nutmeg)

Physical Description: This aromatic evergreen tree grows 9–12 m (30–39 ft) high with spreading branches and a yellow fleshy fruit similar in appearance to an apricot or peach. The ripe fruit splits to expose a single glossy brown nut enclosed by a scarlet aril. The tree produces fruit year round, but the harvest usually occurs in April and November.

Distribution and Ecology: The nutmeg tree is indigenous to the Maluku Province of Indonesia, formerly known as the Spice Islands. The nutmeg tree is grown commercially on the Caribbean islands of Grenada and Trinidad as well as in Central and East Java.

EXPOSURE

Traditional uses of nutmeg include the treatment of rheumatism, cholera, psychosis, stomach cramps, nausea, diarrhea, flatulence, and anxiety in addition to use as an aphrodisiac and an abortifacient. Nutmeg is not used as a narcotic or hallucinogen in traditional Indonesian culture.[4] Although a case report associated the resolution of diarrhea secondary to thyroid medullary carcinoma with the use of nutmeg,[5] there are no approved medical indications for this spice. Nutmeg is a substitute psychotomimetic substance of abuse, particularly for adolescents, students, and prisoners with limited access to other psychotomimetic agents. The unpleasant taste, large doses required for effect, frequent adverse effects, and relative lack of potency as a hallucinogen limit the abuse of nutmeg.[6]

The mature fruit from the nutmeg tree contains a 2.5 cm (1 in.) nut with a bright red, fleshy covering (scarlet aril). Nutmeg is the nut, whereas the dried scarlet aril is called mace. The nut and mace are dried

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

and processed separately. Mace is also a spice, and this spice has been used as an aphrodisiac by physicians in the Near East. There are relatively few reports of poisoning following the ingestion of mace.

PRINCIPAL TOXINS

Structure and Properties

The concentration of active components depends on the botanical source, environmental conditions, storage, and analytical methods. The two oils of nutmeg are fixed oil (expressed oil, nutmeg butter) and essential oil. The fixed oil is an orange, butter-like material obtained by applying heat and hydraulic pressure to nutmeg. This oil contains primarily trimyristin, and the product has no culinary value. Essential oil of nutmeg is a steam distillate that appears as a pale-yellow, nearly colorless liquid with the characteristic odor of spice. Table 9.1 lists some properties of myristicin, which is the main psychoactive constituent of nutmeg. This compound is structurally similar to kawain and related psychoactive constituents of kava (*Piper methysticum* Forst.). Myristicin is also the major component of the aromatic ether fraction of essential oil of mace.[7] Figure 9.1 displays the chemical structure of myristicin.

Poisonous Parts

This essential oil contains from 5–15% volatile oils comprised of about 80% monoterpenes (α-pinene, sabinene, 1,8-*p*-methadiene, β-pinene, 1,4-*p*-menthadiene, camphene), 5% monoterpene alcohols, an aromatic ether fraction, and miscellaneous compounds.[7] The aromatic fraction contains myristicin, elemicin, safrole, and minor constituents (methyleugenol, eugenol, isoeugenol, toluene). The essential oil of nutmeg contains variable amounts (0.1–18%) of methyleugenol, which is a potentially genotoxic compound with DNA-binding potency similar to safrole.[8] Myristicin, elemicin, and safrole account for the majority (85–95%) of the compounds in the aromatic fraction, and myristicin represents about 4–12% of the compounds present in the essential oil.[9] Myristicin is present in plants from the carrot (Umbelliferae) family including dill, celery, parsnip, parsley, and carrot. This compound is also a minor constituent of oil of black pepper (*Piper nigrum*). The estimated intake of myristicin from these sources by the general population is a few mg daily.[10]

TABLE 9.1. Identifying Characteristics and Properties of Myristicin

Property	Value
CAS Number	607-91-0
Chemical name	1-allyl-5-methoxy-3,4-methylenedioxybenzene
Synonyms	Myristicin, methoxysafrole
Empirical formula	$C_{11}H_{12}O_3$
Molecular weight	192.22
Appearance	Colorless oil

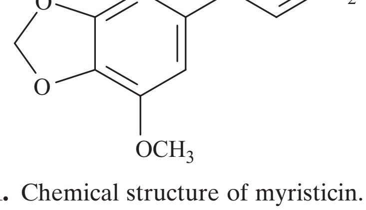

FIGURE 9.1. Chemical structure of myristicin.

Mechanism of Toxicity

Structural similarities of myristicin to classical hallucinogenic compounds (e.g., mescaline) suggest that myristicin may act as a serotonin receptor agonist and hallucinogenic compound. However, the acute toxicity of myristicin is relatively low. Although myristicin comprises the largest fraction (i.e., about 4–8%) of compounds in the aromatic fraction of nutmeg, human studies with myristicin have not duplicated the effects of nutmeg intoxication on the central nervous system.[17] In rodent studies, myristicin and elemicin impair coordination and decreased motor activity.[11] Safrole, eugenol, and isoeugenol do not have similar behavioral effects is these animal studies.

DOSE RESPONSE

One grated nutmeg is approximately one tablespoon and weighs about 6–7 g with typical recreational doses ranging from 5–30 g.[7] The administration of 6 g nutmeg to students did not significantly alter performance on neuropsychological tests.[12] Symptoms do not usually develop following the ingestion of <10 g nutmeg.[7] The ingestion of two whole nutmegs caused moderate toxicity;[1] the ingestion of an estimated dose of 18 g of finely ground nutmeg powder resulted in prolonged periods of obtundation.[13] The ingestion of 25–28 g of nutmeg powder produced tachycardia, anxiety, miosis, paresthesias, palpitations, anticholinergic signs (mydriasis, difficulty voiding, tachycardia), and paranoid behavior without hallucinations.[14,15] The ingestion of an estimated dose of 37 g nutmeg blended in a milkshake was associated with tachycardia, palpitations, drowsiness, nausea, dry mouth, anxiety, restlessness, and agitation without hallucinations.[16] Variation in toxicity may result from the loss of essential oils from the ground nutmeg.

The ingestion of a single dose 400 mg myristicin by 10 subjects was associated with alertness, a feeling of irresponsibility, and euphoria in 2 subjects as well as an unpleasant reaction (anxiety, fear, tremor, nausea, tachycardia) in 2 subjects.[17] Onset of symptoms occurred about 1–2 hours after ingestion and resolved within 24 hours. This dose of myristicin is equivalent to the amount of myristicin present in 40 g of nutmeg.

TOXICOKINETICS

In the 1970s, an *in vitro* study suggested that psychoactive amphetamine derivatives (e.g., 3-methoxy-4,5-methylenedioxyamphetamine, MMDA) are potential metabolites of myristicin.[18] Although the alkenebenzene derivatives, myristicin, elemicin, safrole, are extensively metabolized following ingestion, subsequent studies have not confirmed the presence of amphetamine metabolites. Limited toxicokinetic studies indicate that these alkenebenzene undergo hydroxylation of the side chain, and elemicin undergoes *O*-demethylation prior to hydroxylation. Metabolites detected in the urine of rats fed these compounds include *O*-demethyl elemicin, *O*-demethyl dihydroxy elemicin, demethylenyl myristicin, dihydroxy myristicin, and demethylenyl safrole.[19] *In vivo* animal studies suggest that enzymatic hydrolysis of myristicin produces at least two metabolites (5-allyl-1-methoxy-2,3-dihydroxybenzene, 1′-hydroxymyristicin) that are conjugated and excreted in the urine.[20,21] Amphetamine derivatives were not detected in these two studies.

CLINICAL RESPONSE

The clinical features of nutmeg intoxication resemble belladonna (anticholinergic) toxicity manifest by facial flushing, tachycardia, hypertension, dry mouth, blurred vision, and delirium.[22,23] However, mydriasis is uncommon. Symptoms usually begin about 3–6 hours after ingestion and resolve by 24–36 hours.[6,7] Initially, these symptoms include nausea, vomiting, abdominal pain, chest pain, restlessness, agitation, tremor, ataxia, nystagmus, vertigo, and a feeling of doom. These symptoms occur with alternating periods of lethargy and delirium.[13,24] Other effects of nutmeg intoxication documented in case reports include the sensation of warmth and coldness of the extremities, distortion of space and colors, auditory and tactile hallucinations, headache, and generalized weakness.[25] Patients usually recover without sequelae.[1] The medical literature does not contain any fatalities solely related to nutmeg intoxication since the first decade of the 20th century.[2] There are few data on the reproductive effects of nutmeg. A 29-year old woman, who developed signs of nutmeg intoxication at 30 weeks gestation, delivered a healthy infant at term.[22]

The processing of nutmeg does not usually produce irritative symptoms in spice workers.[26] However, allergic contact dermatitis may develop in workers sensitized to allergens (e.g., isoprenyl myristate) in nutmeg.[27] Occupational asthma may also occur in workers sensitized to spices including mace.[28]

DIAGNOSTIC TESTING

Chromatographic methods easily separate marijuana and the components of nutmeg and mace.[29] Human metabolites of the constituents in nutmeg are detectable by the use of gas chromatography mass spectrometry after acid hydrolysis, liquid-liquid extraction of analytes, and microwave-assisted acetylation of extracted analytes.[19] These metabolites include *O*-demethyl elemicin, *O*-demethyl dihydroxy elemicin, demethylenyl myristicin, dihydroxy myristicin, and demethylenyl safrole. Developing biomarkers for nutmeg intoxication is complicated by limited data on the toxic constituents of nutmeg. Six hours after ingestion 14–21 g nutmeg powder, a 16-year-old adolescent developed tachycardia, drowsiness, dry mouth, warm skin, and mydriasis.[30] The myristicin concentration in a blood sample drawn 8 hours after ingestion was 2 μg/mL. The postmortem blood from a 55-year-old woman contained 4 μg/mL of myristicin and 0.072 μg/mL of flunitrazepam.[30] Death was attributed to the combination of the two substances. However, myristicin does not necessarily account for the toxic effects of nutmeg, and the contribution of myristicin and nutmeg to this death remains speculative. Routine laboratory tests during nutmeg intoxication are usually normal.[24] The ingestion of nutmeg does not produce positive urine drug screens.[14]

TREATMENT

Management is usually supportive. The presence of hemodynamic instability suggests the presence of other toxins or illnesses. Decontamination measures are usually unnecessary because of the presence of vomiting or delayed contact (i.e., >1–2 hours after ingestion) with the health care facility. There are no clinical data to guide management of nutmeg intoxication. The use of standard antiemetics (prochlorperazine, trimethobenzamide, odansetron, metoclopramide) and intravenous fluids may be required to treat protracted nausea and vomiting. Sedatives (diazepam, haloperidol) should be used with caution because of alternating periods of delirium and obtundation during nutmeg intoxication.

Chapter 10

PEPPER and CAPSAICIN
(*Capsicum* and *Piper* Species)

HISTORY

Mexican Indians probably used chili peppers long before the birth of Christ.[1] The archaeologist, R. S. Macneish, found pepper seeds dating from about 7500 BC in Mexico.[2] The physician, Chauca, on the second voyage of Columbus to the New World noted the culinary and medicinal use of chili peppers by Native Americans. Irritant smoke from the burning of chili peppers was a weapon used by Native Americans against invaders. Chemical investigations into the ingredients in chili peppers began in the early 19th century. In 1846, Thresh crystallized the active component in chili peppers, and he named the substance capsaicin.[3] Nelson and Dawson determined the chemical structure of capsaicin in the early 20th century.[4,5]

BOTANICAL DESCRIPTION

There are a variety of *Capsicum* peppers beside the common *C. annuum* L. (cayenne pepper, chili pepper) including *C. baccatum* L. (aji, aji amarillo, locoto), *C. chinense* Jacq. (aji dulce, habanero, rica red), and *C. pubescens* Ruiz & Pavón (rocoto, manzano).

Common Name: chili pepper, red pepper, Christmas pepper, Tabasco pepper, cayenne pepper

Scientific Name: *Capsicum annuum* L. (*Capsicum frutescens*)

Botanical Family: Solanaceae

Physical Description: This annual plant has densely branched stems that reach up to 1.5 m (5 ft) in length. Single, white flowers produce small fruit in the fall. The fruit changes from white to shades of yellow, orange, and red as the fruit matures.

Distribution and Ecology: This pepper is a native species of South America that is now cultivated worldwide in warm, dry climates.

Common Name: Black pepper (ripe), white pepper (unripe)

Scientific Name: *Piper nigrum* L.

Botanical Family: Piperaceae (pepper)

There are a large number of pepper species in the genus *Piper* including *P. auritum* Kunth (Vera Cruz pepper, Mexican pepperleaf), *P. jacquemontianum* Kunth (Caracas pepper), *P. glabrescens* (Miq.) C. DC. (Guyanese pepper), *P. hispidum* Sw. (Jamaican pepper), *P. longum* L. (Indian long pepper), *P. marginatum* Jacq. (marigold pepper), and *P. retrofractum* Vahl (Javanese long pepper).

Physical Description: This perennial vine has smooth, round, woody, branched stems that reach up to 4 m (13 ft) in length. The leaves are broad-ovate, smooth, and dark green; and sheath-like petioles attach the leaves to joints in the branches. The small, white flowers produce globular, sessile drupes, which turn red on maturity.

Distribution and Ecology: This pepper plant is a native species of India and Sri Lanka. It is cultivated widely in the tropical areas of China, India, Indonesia, and the Philippines. These plants do not tolerate frost.

EXPOSURE

Chili peppers are the pungent fruits of various species of the genus *Capsicum* that are grown as condiments, spices, ornamentals, and pharmaceutical preparations (i.e., counterirritant in external analgesic preparations). Some dog-repellent products and pepper sprays contain up to 10% oleoresin capsicum as well as other capsaicinoid compounds.[6] Pepper spray is a chemical irritant that has been available commercially since the 1970s as an aerosol to temporarily disable assailants. Increasing the concentration of capsaicin prolongs the irritant effects of the spray rather than increasing the initial response.[7] Capsaicin-containing creams are used for the treatment of painful conditions, such as psoriasis, rheumatoid arthritis, diabetic neuropathy, postherpetic neuralgia, postmastectomy syndrome, cluster headache, and reflex sympathetic dystrophy. For the treatment of these conditions, the exact role of capsaicin compared with other analgesics remains undefined.[8] An evidence-based review of the efficacy of capsaicin in chronic pain suggests that topical capsaicin is useful only for a small number of patients who do not respond to conventional analgesics.[9] Capsaicin is not a traditional counterirritant like oleoresin capsicum, which contains only trace amounts of capsaicin.

PRINCIPAL TOXINS

Structure and Properties

Chili Peppers and Capsaicin

Capsaicin (trans-8-methyl-*N*-vanillyn-6-noneamide, CAS RN: 404-86-4) is the major alkaloid responsible for the mucosal irritant properties of plant species from the genus *Capsicum*.[10] The molecular weight of capsaicin is 305.4 Da, and the molecular formula is $C_{18}H_{27}NO_3$. Other compounds in chili pepper include homologous branched- and straight-chain alkyl vanillylamides (i.e., capsaicinoid compounds) such as dihydrocapsaicin, nordihydrocapsaicin, homocapsaicin, and homodihydrocapsaicin.[11] These compounds also possess pungent properties. Nonivamide (CAS RN: 2444-46-4) is a chemical structurally similar to capsaicin with a molecular formula of $C_{17}H_{27}NO_3$. Although sometimes termed "synthetic capsaicin," nonivamide possesses slightly less pungent properties compared with capsaicin.[12] Civamide is a synthetic chemical (CAS RN: 25775-90-0) that is the *cis*-isomer of capsaicin.

Capsaicin is soluble in ethanol, acetone, and fatty oils, but this compound is insoluble in cold water. The concentrations of these capsaicinoid compounds in chili peppers are much smaller (i.e., 0.1–1%) than capsaicin.[12] The aroma from the roasting of red pepper seed oil results from the formation of pyrazine compounds (e.g., 2,5-dimethylpyrazine).[13] Aflatoxins may contaminate seeds of black pepper.[14]

Oleoresin Capsicum

Oleoresin capsicum is a complex mixture of a variety of branched- and straight-chained alkyl vanillylamides with capsaicin being the principal constituent.[15] There are over 100 compounds in this mixture, which is extracted from dried, ripe fruit of chili peppers (*Capsicum annuum*). The actual composition depends on the environmental conditions, season, maturity of the fruit, and the extraction process. Depending on the variety of chili pepper, oleoresin capsicum contains about 0.01–1% capsaicinoids (vanillylamides) on a dry mass basis.[16] The approximate distribution of these capsaicinoid compounds is as follows: capsaicin, 70%; dihydrocapsaicin, 20%; norhydrocapsaicin, 7%, homocapsaicin, 1%, and monodihydrocapsaicin, 1%. Commercial pepper sprays with oleoresin capsicum contain a variety of natural and synthetic capsaicinoid compounds depending on the formulation and source. Brands of pepper spray intended for sale to the general public contains ≤1% oleoresin capsicum; law enforcement products typically contain 5–10% oleoresin capsicum. Capsaicin is usually the active ingredient of these formulations along with other capsaicinoid compounds (dihydrocapsaicin, nordihydrocapsaicin, nonivamide). Analysis of two samples of commercial pepper spray yielded a total of 10.1 mg/mL and 19.8 mg/mL capsaicinoid compounds with capsaicin accounting for 3.6 mg/mL and 8.5 mg/mL of the content, respectively.[6] The other major capsaicinoid compound in the spray was dihydrocapsaicin, which possesses pungent properties similar to capsaicin.

Black Pepper

The active ingredient in black pepper is piperine (1-piperoylpiperidine), the amide of the alkaloid piperidine, and the concentration of this compound varies substantially between *Piper* species.[17] Piperine accounts for about one-half of the nonvolatile ether extract of black pepper.[18] Safrole is a minor constituent of *P. nigrum* at an approximate concentration of 0.1%.[19]

Poisonous Parts

Capsicum is the dried, ripe fruit of *Capsicum annuum*, and capsaicin is the purified chemical that is the active ingredient in capsicum. Capsaicin content increases with maturation of the fruit.[20] In general, the capsaicin

content of chili peppers is <1% dry weight. Capsicum oleoresin is a thick, dark reddish-brown liquid concentrate produced by the extraction of fruits with volatile solvents. This liquid contains over 100 chemicals (e.g., alcohols, carbonyls, carboxylic acids, esters, pyrazine compounds, terpenes) in the volatile component of the resin. However, the capsaicin content of the oleoresin is highly variable, and the oleoresin does not uniformly mediate substance P release.[12] This neuropeptide causes vasodilation due to the release of nitric oxide from the endothelium.

Mechanism of Toxicity

The medical effects of capsaicin result form the initial period of intense excitation of primary afferent sensory nerves followed by a prolonged period of relative resistance to nociceptive chemical stimuli. Capsaicin reduces the transmission of painful impulses from the periphery to the central nervous system by depleting substance P in sensory neurons, particularly in unmyelinated C-type and some myelinated A delta-type nerve fibers.[10] Physiologically, capsaicin reduces vasodilation and heat pain thresholds, leading to increased pain sensitivity.[21] Repeat exposure to capsaicin causes desensitization to the stimulatory effect on sensory nerves.[22]

In volunteer studies, both red pepper and black pepper increase parietal and pepsin secretions, potassium loss, and the exfoliation of gastric cells.[23] The clinical consequences of these changes are not known. Although there is substantial interindividual variation, these studies suggest that gastrointestinal hemorrhage may occur after the ingestion of black or red peppers. However, there are inadequate clinical data to determine the effect of the chronic consumption of peppers on the gastric mucosa.

DOSE RESPONSE

Chili peppers are edible and nontoxic in the usual doses.

TOXICOKINETICS

There are limited data on the toxicokinetics of capsaicin and capsaicinoid compounds in humans. Analysis of breast milk indicates that piperine is excreted in breast milk following the ingestion of black pepper.[24]

CLINICAL RESPONSE

Chili (Cayenne) Pepper

Ingestion

Contact with products containing capsaicin produces local irritation and lacrimation. A case series of five contestants in a jalapeno pepper-eating contest associated the ingestion of large quantities of jalapeno peppers with lacrimation, rhinorrhea, dysuria, and burning discomfort on defecation within 24 hours.[25] The eponym “jalaproctitis” was given to this syndrome, which also occurs in children abused with jalapeno peppers.[26]

The potential metabolism of capsaicinoid compounds to highly reactive intermediates (phenoxyl radicals, arene oxides) and the high incidence of gastric cancer in populations consuming relative large amounts of jalapeno peppers suggests the possibility of genotoxicity and/or carcinogenicity following the chronic consumption of chili peppers.[27] A population-based case-control study in Mexico City compared the risk of gastric cancer in chili pepper consumers and nonconsumers.[28] The odds ratio for gastric cancer was increased (OR = 5.49, 95% CI = 2.72–11.06) in chili pepper consumers compared with age- and sex-adjusted controls (nonconsumers). The odds ratio for gastric cancer demonstrated a dose-response relationship for the amount of chili peppers consumed, but not for the frequency of consumption. Animal studies do not consistently demonstrate carcinogenic effects following chronic consumption of chili peppers. Beginning at the age of 6 weeks, 0.03125% capsaicin was administered in a semisynthetic powdered diet for the lifespan of Swiss mice.[29] Although there was an increased incidence of benign polypoid adenomas in the cecum, the rate of malignant tumors in the treated and control groups was similar.

Dermal Exposure

The most common symptoms reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System after reported exposure to *Capsicum annum* were mucous membrane irritation (oral, dermal, ocular, throat), rash (erythema, hives), and pruritus.[30] In this case series, exposure to chili peppers was based on historical reports, and there was no independent confirmation. Case reports associate exposure to dried red chili peppers (*Capsicum annum* cultivar) with severe burning of abraded fingertips. The eponym “Hunan hand” was given to this syndrome, which results from the effect of capsaicin on dermal pain fibers.[21,31] Rare case reports associate dermal exposure to jalapeno peppers with acute febrile neutrophilic dermatosis

(Sweet's syndrome) characterized by painful erythematous papules, plaques, pustules, and hemorrhagic bullae on the hands.[32]

Inhalation

The most common symptoms reported to poison control centers following contact with pepper sprays involve irritation of the eyes, skin, and upper respiratory tract.[33] Contact with pepper spray produces local inflammation, erythema, and pain in the skin and conjunctiva with transient reduction in visual acuity resulting from secondary tearing. Symptoms usually resolve within one-half hour to 2 hours after decontamination.[34] Although exposure to capsaicin causes cough and a transient increase in airway resistance, experimental studies and case series do not indicate that patients with bronchial hypersensitivity are substantially more susceptible to the irritant effects of pepper spray than patients without bronchial hypersensitivity.[34,35] Experimental studies demonstrate that some asthmatic patients may develop a transient decrease in expiratory flow rates (e.g., FEV_1), but there is no direct correlation between methacholine and capsaicin responses in the bronchioles.[36] There is little clinical evidence that the use of standard doses of oleoresin capsicum spray significantly reduces oxygen saturation or ventilation in healthy subjects. A controlled clinical trial involving 35 healthy subjects sprayed with oleoresin capsicum did not detect significant changes in the mean percent predicted forced vital capacity (FVC), percent predicted forced expiratory volume in 1 second (FEV_1), oxygen saturation, or end-tidal CO_2 concentration, when compared with population norms.[37] There is a progressive mild restriction of pulmonary function with changes in position from sitting to supine, prone, and restraint positions. In this study, the use of the prone maximum restraint position reduced the FVC and FEV_1 by approximately 15% compared with the sitting position, but there was no statistically significant difference in these parameters between the use of oleoresin capsicum and controls in the restraint position. Furthermore, there was no clinically significant impairment of ventilation.

Serious complications following exposure to pepper spray are rare,[38] and case reports usually involve the direct aspiration of the spray. An 11-year-old child directly inhaled a jet spray from a pressurized container containing capsaicin spray.[39] He recovered after developing subglottic obstruction of the trachea and bilateral pulmonary infiltrates that required intubation. Signs of clinically significant airway edema included drooling, expiratory wheezing, stridor, and use of accessory muscles. The accidental discharge of pepper spray next to a 4-week-old infant produced life-threatening respiratory distress followed by the development of copious bronchial secretions, pneumonia, and progressive respiratory failure.[40] The infant survived after receiving extracorporeal membrane oxygenation. Corneal abrasions may complicate the use of pepper spray.[41] Case reports document the temporal association between the use of pepper spray and death during police custody.[7] However, the causal role of pepper spray in these deaths is unclear because of the multiple etiologies of "in-custody" deaths and the lack of significant changes in respiratory parameters following use of the pepper spray.

Occupational Exposure

The inhalation of capsaicin in red pepper produces coughing in a dose-dependent relationship.[42] A cross-sectional study of workers exposed to capsaicin detected a statistically significant increase in complaints of cough in capsaicin-exposed workers compared with nonexposed controls.[43] There was no significant difference in measures of pulmonary function (FEV_1, FVC) between the two groups.

Black Pepper

Aspiration of black pepper is a rare cause of respiratory distress, and case reports indicate that the aspiration of large amounts of black pepper can produce airway obstruction and hypoxia. The aspiration of black pepper by a child with a history of pica resulted in respiratory distress, asphyxia, and cardiopulmonary arrest.[44] The child died 4 days later when respiratory support was withdrawn. Several case reports document child abuse associated with the fatal, intrapharyngeal administration and aspiration of black pepper.[45,46] A 21-month-old infant developed respiratory distress and thick, copious, bronchial secretions after the accidental aspiration of an unknown amount of pepper.[47] She survived after intensive care that included intubation and tracheostomy.

DIAGNOSTIC TESTING

UV spectrophotometric methods are relatively specific tests for the presence of the active ingredient in black pepper, piperine. However, UV spectrophotometric methods provide slightly higher piperine content compared with reverse phase high performance liquid chromatography (HPLC).[18] Gas chromatographic methods are available to separate capsaicinoid compounds, such as nonivamide.[48] Following separation of capsaicinoid compounds in blood samples by reversed phase HPLC and identification by tandem mass spectrometry, the limit of detection (LOD) and lower limit of quantitation

(LLOQ) were 0.25 mg/mL and 1.0 mg/mL, respectively, for the major capsaicinoid compounds (capsaicin, dihydrocapsaicin, nonivamide).[49]

TREATMENT

Management of symptoms associated with exposure to capsaicin is supportive. Decontamination involves cleansing of the eyes and affected skin with water (i.e., at least 1–2 L saline). Cases of aspiration may require bronchoscopy and pulmonary lavage. There are limited clinical data regarding the optimal treatment of the paraesthesias associated with peppers. Options for the treatment of the dermal pain associated with capsaicin include immersion in milk, cold water, topical lidocaine gel, vegetable oil, or vinegar (5% acetic acid).[50,51] Although immersion in cold water initially provided better relief of pain associated with peeling green chili (*C. annum*), *complete* immersion in vegetable oil provides greater long-term relief than cold water as measured by a visual analog scale.[52] Prolonged immersion (i.e., several hours) may be necessary for severe cases. A pilot study on the use of magnesium-aluminum hydroxide suspension (Maalox®, Novartis, East Hanover, NJ) suggested that the immediate application of this compound reduces pain associated with commercial defensive spray containing 10% capsaicin during the first 30 minutes, but pain scores did not differ between the treatment and saline control group after 60 minutes postexposure.[53] Rodent studies suggest that bismuth subsalicylate can reduce the dyspepsia and gastric pain associated with the consumption of peppers.[54] Corneal abrasions may complicate the use of pepper spray. If a corneal abrasion cannot be excluded clinically after decontamination measures, the cornea should be examined with fluorescein staining by a Wood's lamp or slit lamp.

Chapter 11

POTATOES, TOMATOES, and SOLANINE TOXICITY
(*Solanum tuberosum* L., *Solanum lycopersicum* L.)

HISTORY

The Inca people first cultivated the potato in the Altiplano of the High Andes of Chile during prehistoric times.[1] Spanish explorers brought the potato to Europe near the end of the 16th century. Although initially considered "peasant food," the cultivation of the potato spread across Europe including continental Europe, Britain, and Ireland. By 1780, the potato became a staple crop in Ireland. Although cultivation of the potato contributed to the rapid expansion of the Irish population between 1750 and 1850, a famine began in the late 1840s as a result of a fungal-induced potato blight [*Phytophthora infestans* (Mont.) de Bary]. During The Great Hunger in Ireland between 1845 and 1852, approximately one million deaths occurred along with the migration of 1.5 million people.[1] The creation of new transgenic potato cultivars with increased resistance against phytopathogens and improved composition of nutrients is an area of active research.

Although the toxicity of plants (e.g., deadly nightshade, henbane) from the nightshade (Solanaceae) family has been known since ancient times, toxicity from members of the *Solanum* genus (e.g., potato, tomato) has been documented only in modern times. Solanine intoxication is relatively rare considering the frequent use of potatoes and tomatoes as food staples. Outbreaks of solanine poisoning occur primarily when toxic glycoalkaloid concentrations increase substantially in commercial potatoes. Most sporadic cases of solanine toxicity involve children ingesting poisonous wild plant parts.[2]

BOTANICAL DESCRIPTION

Sweet potatoes [*Ipomoea batatas* (L.) Lam.] are a seasonal crop grown in tropical and subtropical regions, primarily for human consumption of the fresh or dried tubers. This South American native is a member of the morning glory family (Convolvulaceae) rather than the potato family. Sweet potatoes are widely cultivated in warm areas throughout the world as annual herbaceous plants. Three closely related, cultivated species of eggplant include *Solanum macrocarpon* L. (gboma eggplant), *Solanum aethiopicum* L. (scarlet eggplant, Ethiopian nightshade), and *Solanum melongena* L. (brinjal or aubergine eggplant).[3]

Common Name: Garden tomato

Scientific Name: *Solanum lycopersicum* L.

Botanical Family: Solanaceae (potato)

Physical Description: This herbaceous perennial plant produces a large berry with 2–12 locules that contain many small seeds. Most varieties of tomatoes are red when mature.

Distribution and Ecology: The tomato plant was originally cultivated in Mexico and Peru. European explorers brought seeds to Europe, and the tomato is now widely grown in temperate climates throughout the world.

Common Name: Eggplant, aubergine, brinjal

Scientific Name: *Solanum melongena* L.

Botanical Family: Solanaceae (potato)

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Physical Description: This hairy, erect, annual, herbaceous plant reaches up to 1 m (about 3 ft) in height. The branched stems contain alternate, petiolate leaves with an ovate-elliptic shape. The flowers have a lobed calyx and a tubular, violet corolla. The fruit is a large ellipsoid berry that contains many brown seeds and turns purple when mature.

Distribution and Ecology: This perennial, frost-tender plant requires sunny and moist conditions. This species of eggplant is cultivated worldwide. Major areas of cultivation include China, Turkey, Japan, Mexico, Greece, Egypt, and Syria.

Common Name: Irish potato

Scientific Name: *Solanum tuberosum* L.

Botanical Family: Solanaceae (potato)

Physical Description: These annual, sprawling plants produce lavender to white flowers with yellow stamen. The relatively weak stems reach up to about 1 m (about 3 ft) in length with long pinnate leaves and ovate leaflets.

Distribution and Ecology: The potato is widely cultivated in temperate regions for the edible underground tubers.

EXPOSURE

The genus *Solanum* contains a number of food-producing species including eggplant (*S. melongena*), potatoes (*S. tuberosum*), and tomatoes (*S. lycopersicum*). African societies use the cholinesterase-lowering activity of solanine and chaconine in potatoes for the traditional treatment of human immunodeficiency virus (HIV) infections. Some communities (e.g., Bangladesh immigrants in the UK) use tomato leaves as a food source without obvious toxicity.

PRINCIPAL TOXINS

Structure and Properties

Glycoalkaloids are natural plant glycosides that contain nitrogen in a steroidal structure (aglycone) and a carbohydrate side chain at the 3-OH position. The hexacyclic alkaloid aglycones are derived from cholesterol. Species of the genus *Solanum* that contain glycoalkaloids include the potato (α-solanine, α-chaconine), the tomato (α-tomatine, dehydrotomatine), and the eggplant (solasonine, solamargine).[4] Table 11.1 lists the basic glycoalkaloids and the corresponding steroid skeleton (aglycone) for potatoes, tomatoes, and eggplants. The glycoalkaloid content varies substantially between different cultivars depending on the strain and postharvest conditions (light, mechanical injury, storage). Potatoes may also contain small amounts of the glycoalkaloid hydrolysis products (β- and γ-chaconines, β- and γ-solanines) and solanidine.[5] Food processing (cooking, baking, frying) does not significantly alter the glycoalkaloid content. Boiling removed <3.5% of the main glycoalkaloids in potatoes, whereas microwaving decreases the concentrations of these compounds about 15%.[5] Significant degradation of these glycoalkaloids begins at temperatures above 170 °C (338 °F), and deep-frying at 150 °C (302 °F) does not significantly alter the concentrations of these glycoalkaloids. Heating potatoes to 210 °C (410 °F) for 10 minutes reduces the α-chaconine and α-solanine concentrations about 40%.[5] Potatoes and eggplants also contain water-soluble nortropane alkaloids, such as calystegine A_3 and calystegine B_2.[6] There are few data on the human toxicity of these nortropane alkaloids.

TABLE 11.1. Glycoalkaloid Structure of Food Products from Genus Solanum

Plant	Scientific Name	Aglycone Skeleton	Glycoalkaloid
Potato	*Solanum tuberosum*	Solanidine	α-chaconine, α-solanine
Tomato	*Solanum lycopersicum*	Tomatidine	α-tomatine, dehydrotomatine
Eggplant	*Solanum melongena*	Solasodine	Solamargine, solasonine

Potatoes

Glycoalkaloids occur in all parts of potato plants including tubers, roots, sprouts, and leaves. In general, glycoalkaloids are α-compounds, whereas enzymatic or acid hydrolysis of the trisaccharide side chains of these glycoalkaloids produces β- and γ-compounds. The two major glycoalkaloids, α-solanine and α-chaconine, share the same aglycone (solanidine), but these two glycoalkaloids differ with respect to the composition of the sugar side-chain. α-Solanine (CAS RN: 20562-02-1, $C_{45}H_{73}NO_{15}$) is a tri-glycoside compound composed of galactose, glucose, and rhamnose, whereas α-chaconine is composed of glucose and two rhamnose moieties. Accumulation of glycoalkaloids stops after processing, but home processing (baking, boiling, frying, microwaving) does not eliminate significant amounts of glycoalkaloids from the potato.[7] Solanine is practically insoluble in water. Table 11.2 lists some of the physical properties of solanine.

TABLE 11.2. Some Physical Properties of Solanine

Physical Property	Value
Melting point	285 °C[a]
Log P (octanol-water)	2.000
Water solubility	1.380 mg/L (25 °C)
Vapor pressure	1.67E-34 mmHg (25 °C)
Henry's Law Constant	1.22E-31 atm m^3/mole (25 °C)
Atmospheric OH rate constant	3.72E-10 cm^3 molecule/second (25 °C)

[a]Decomposes at this temperature.

Tomatoes

Tomatidine is the basic aglycone for the glycoalkaloids, α-tomatine and dehydrotomatine, in the tomato plant. These glycoalkaloids probably aid the defense of the tomato plant against bacteria, fungi, viruses, and insects.

Eggplant

Eggplant fruit contains a relatively large amount of antioxidant phenolic compounds, primarily hydroxycinnamic acid conjugates such as chlorogenic and dicaffeoylquinic acids.[8]

Poisonous Parts

Although the sweet potatoes contain low concentrations of a potentially toxic furanoterpenoid (ipomearone),[9] consumption of sweet potatoes has not been associated with human toxicity.

Potato

Although glycoalkaloids are present throughout the potato plant, the highest concentrations occur in the foliage, blossoms, periderm, cortex, and areas of high metabolic activity (e.g., eyes, green skin, stems, sprouts) followed by the peel and the tuber. α-Chaconine and α-solanine represent up to 95% of the glycoalkaloid content in potato tubers, and the general term solanine typically describes the glycoalkaloids present in *Solanum tuberosum*.[10] The glycoalkaloid concentration varies due to environmental and genetic factors. Ripe fruits contain the least amount of solanine. Factors that increase the solanine concentrations include physical injury to the plant, specific species (e.g., potato cultivar Lenape), physiological stress, immaturity (i.e., green potato), low storage temperature, and storage in bright lighting.[11]

The typical ratio of α-chaconine to α-solanine in the tuber is about 60:40. The glycoalkaloid content of peels is substantially higher than tubers, particularly α-chaconine. In a study of Mexican potatoes, the peel always contained higher total glycoalkaloid concentrations than the tuber, and α-chaconine accounted for 65–71% of the total content of glycoalkaloids.[12] Potato leaves also contain higher concentrations of glycoalkaloids than the tubers, particularly α-chaconine. In a study of UK potatoes, the leaves contained 0.06–55.7 mg α-chaconine/100 g and 0.64–22.6 mg α-solanine/100 g.[13] Unprocessed tubers contained 0.3–0.63 mg α-chaconine/100 g and 0.05–0.65 mg α-solanine/100 g.

Normally, potato tubers (*Solanum tuberosum*) contain low concentrations of toxic glycoalkaloids (e.g., solanine) unless adverse storage conditions or cultivation methods increase the solanine content. In a study of Mexican potatoes, the glycoalkaloid content of boiled peeled potatoes ranged from nondetectable to 9 mg/100 g fresh weight.[12] Because of the bitter taste of the alkaloids, solanine poisoning is rare except in times of food shortages when stressed or green potatoes are consumed. Normal food processing methods (baking, frying, broiling, microwaving) do not remove substantial amounts of glycoalkaloids from potatoes.[14] In a study of 20 commercial potato products, the α-chaconine and α-solanine content was lowest in canned boiled potatoes (0.04–0.08 mg/100 g and 0.04–0.06 mg/100 g, respectively) and highest in deep fat fried peels (93.1–97.9 mg/100 g and 46.1–48.0 mg/100 g, respectively).[15] The α-chaconine and α-solanine concentrations of individual commercial potato products were similar. The boiling of sprouted potatoes allows the diffusion of glycoalkaloids from the sprouts to the tuber and therefore increases the glycoalkaloid content of the tuber.[16]

Tomato

Tomato leaves and vines contain glycoalkaloids similar to solanine, but toxic glycoalkaloids are not usually detectable in the fruit. As listed in Table 11.3, the glycoalkaloid content varies between plant part and the type of glycoalkaloid. Approximately 72% of the original amount of α-tomatine remained after the preparation of Southern fried green tomatoes using traditional cooking methods.[17] In a study of three tomato plants, the ratio of mean concentrations of α-tomatine to dehydrotomatine ranged from 4.7 in the stems and flowers to 10.9 in green fruit as measured by high performance liquid chromatography (HPLC) with UV detection.[18] There were trace amounts of glycoalkaloid compounds in the roots and nondetectable concentrations in mature fruit.

TABLE 11.3. Glycoalkaloid Content in Various Parts of the Tomato Plant

Tomato Part	Dehydrotomatine[a]	α-Tomatine[a]
Fruit (green)	1498 ± 49	16,285 ± 112
Fruit (red)	ND	ND
Flowers	1023 ± 3	4,825 ± 191
Calyxes	370 ± 17	2,870 ± 129
Leaves	304 ± 15	1,847 ± 112
Stems	331 ± 4	1,547 ± 32
Roots	Trace	Trace

Source: Data from Ref 18.
[a]Mean ± standard deviation of three samples expressed as μg/g fresh weight; ND, nondetectable.

Mechanism of Toxicity

In vitro studies indicate that both α-solanine and α-chaconine are reversible inhibitors of human plasma cholinesterase (butyrylcholinesterase).[19] In a study of rabbits, intraperitoneal doses of solanine caused mild to moderate inhibition of both specific and nonspecific cholinesterases.[20] The relevance of plasma cholinesterase inhibition to human solanine toxicity is unclear because solanine toxicity in not classically associated with a cholinergic syndrome. In experimental animals, α-solanine and α-chaconine also demonstrate cytotoxic properties.[13,21]

DOSE RESPONSE

In animal models, the toxicity of solanine depends on the dose, species, and route of administration with the parenteral route much more toxic than the oral route of exposure.[22] Volunteer studies using taste panels suggest that a bitter taste and burning sensation in the mouth occurs when the glycoalkaloid content of potatoes exceeds 14 mg/100 g and 22 mg/100 g fresh weight, respectively.[23,24] The presence of total glycoalkaloid content exceeding 60 mg/100 g fresh weight produces strong bitterness and burning.[25] The total glycoalkaloid content of most commercial potatoes does not usually exceed 10 mg/100 g. The US Food & Drug Administration (FDA) limits solanine content in potatoes to ≤20 mg/100 g potatoes.

TOXICOKINETICS

Animal studies indicate that the absorption of solanine from the gastrointestinal tract is poor, and solanine distributes in the highest concentration to the spleen with progressively lower concentrations in the kidney, liver, lung, fat, heart, brain, and blood.[26] In a study of seven healthy volunteers, the ingestion of mashed potatoes containing glycoalkaloid concentrations of 1 mg/kg (α-solanine:α-chaconine ratio = 41:59) produced peak serum α-solanine and α-chaconine concentrations at approximately 5 ± 1 hours and 6 ± 1 hours, respectively.[27] The biological half-lives of α-solanine and α-chaconine in serum samples were about 11 hours and 19 hours, respectively. The stomach hydrolyzes solanine to the less toxic glycoalkaloid, solanidine. Elimination occurs rapidly in the feces and to a lesser extent in urine. Animal studies indicate that the gastrointestinal tract also poorly absorbs α-chaconine with excretion occurring rapidly in the feces, probably by biliary excretion.[28] The elimination of α-chaconine and α-solanine is similar with the major metabolite being the aglycone, solanidine. Figure 11.1 demonstrates the degradation of major glycoalkaloids in the potato.

CLINICAL RESPONSE

Clinical features of solanine poisoning include gastrointestinal and neurologic symptoms, particularly vomiting, headache, and flushing. The glycoalkaloid content of young leaves is substantially higher than the tubers;[13] therefore, ingestion of the above-ground portion of these plants can cause gastrointestinal distress. The largest series of solanine poisoning involved an English day school where 78 schoolboys developed diarrhea and vomiting after eating potatoes stored since the summer term.[29] Symptoms began 7–19 hours after ingestion with vomiting, diarrhea, anorexia, and malaise. Of the 78 boys, 17 were admitted to the hospital. Other symptoms included fever (88%), altered mental status (drowsiness, confusion, delirium) (82%), restlessness (47%), headache (29%), and hallucinations (23%). Three boys were seriously ill with hypotension, tachycardia, and stupor out of proportion to fluid and electrolyte imbalance. These boys were discharged 6–11 days after admission, and they had nonspecific symptoms and visual blurring for several weeks after release from the hospital.

Fatalities from solanine poisoning are not well documented in the modern medical literature. Deaths have been associated with consumption of toxic potatoes, but those reports involved malnourished patients who may not have received adequate care.[30] Headache, abdominal pain, vomiting, thirst, restlessness, and apathy preceded death, but no convulsions or fever were reported. There is no conclusive data that constituents of potatoes or tomatoes are teratogenic to humans.[31] In studies of hamsters, acute maternal toxicity limited the administration of dosages high enough to induce statistically significant levels of terata in litters receiving α-chaconine and α-solanine.[32] However, the administration of toxic doses of the aglycone solanidine and the derivative

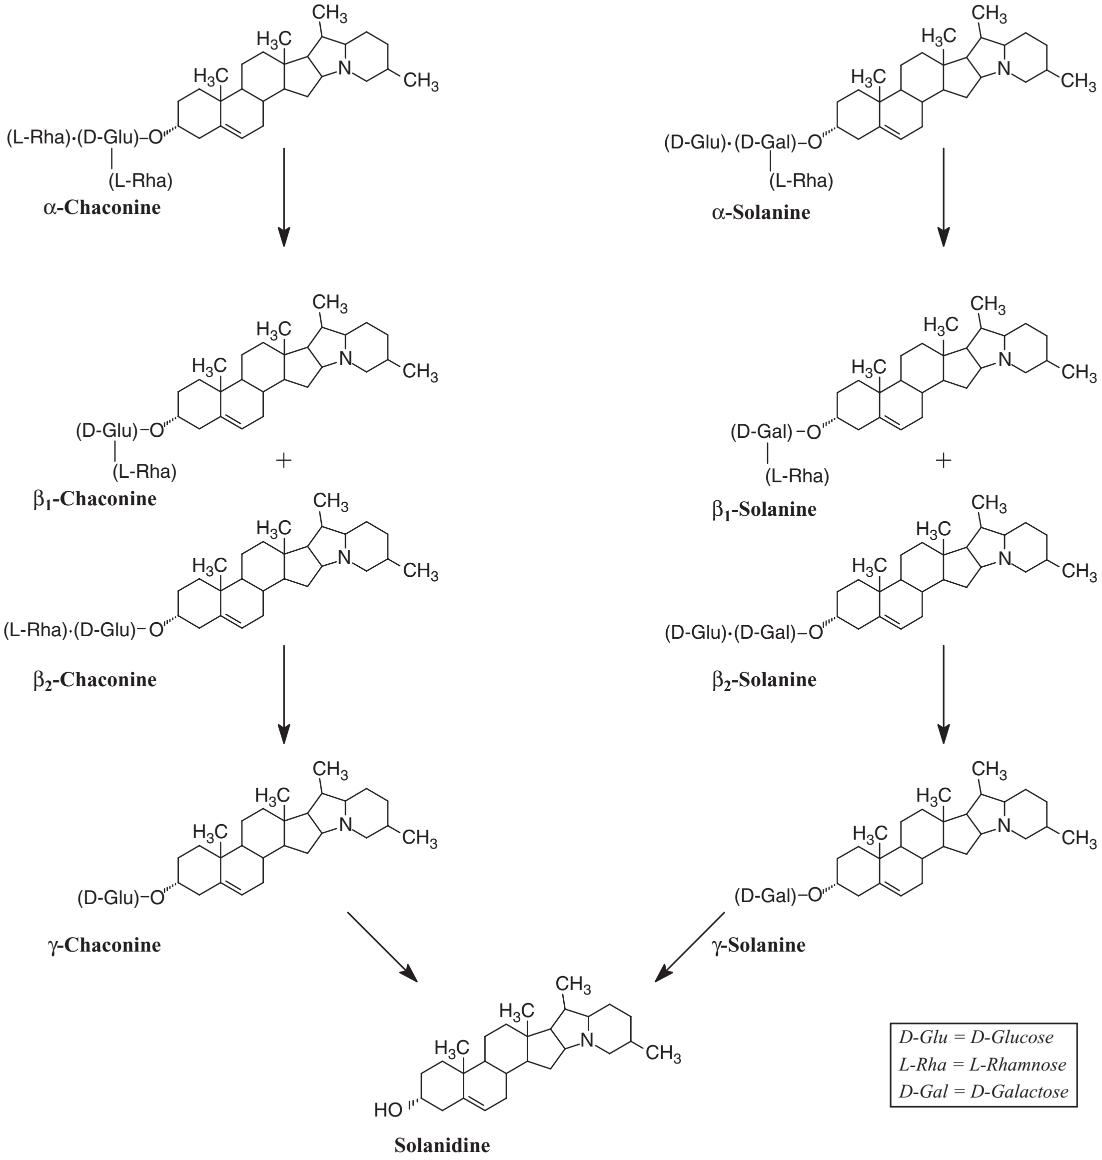

FIGURE 11.1. Hydrolysis of the trisaccharide side chains of potato glycoalkaloids α-chaconine and α-solanine to the aglycone solanidine. Adapted from Friedman M, et al. Postharvest changes in glycoalkaloid content of potatoes. Adv Exp Med Biol 1999;459:124.

solanidine *N*-oxide produced a statistically significant ($p < 0.005$) increase in the incidence of malformations. Although teas brewed from the tomato plant have been associated with solanine-like poisoning in some reference books,[33] there are few data that indicate tomatoes cause toxicity.

DIAGNOSTIC TESTING

Methods for the detection and quantitation of glycoalkaloids include gas chromatography,[34] high performance liquid chromatography (HPLC),[35,36] HPLC with electrospray ionization and tandem mass spectrometry,[37] and gas chromatography mass spectrometry.[38] Enzyme-linked immunosorbent assay (ELISA) methods allow the rapid determination of glycoalkaloid content in plant parts from the potato including the tuber.[39] HPLC is commonly used for the determination of glycoalkaloid content of fresh and processed potatoes, including the concentration of individual glycoalkaloids in various plant parts. The limits of detection for individual glycoalkaloids in serum are about 0.3 ng/mL as determined by HPLC.[27] The AOAC International (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) official method of analysis for glycoalkaloids in potato tubers involves

HPLC with ultraviolet detection (HPLC/UV).[40] The analytical range for this method is 10–200 mg α-solanine/kg and 20–250 mg α-chaconine/kg. Following the ingestion of approximately 0.41 mg α-solanine/kg body weight and 0.59 mg α-chaconine/kg body weight, the mean peak concentration of these glycoalkaloids were about 8 ng/mL and 14 ng/mL, respectively.[27] In general, glycoalkaloid content of potatoes should not exceed 200 mg/kg fresh potatoes.

TREATMENT

The treatment of solanine poisoning is entirely supportive. Most patients with solanine poisoning develop vomiting and diarrhea; therefore, decontamination measures are not usually necessary. There are no clinical or experimental data to indicate that decontamination measures improve outcome during solanine poisoning. Dehydration and electrolyte imbalance are the most common serious complications of solanine poisoning, and patients with substantial vomiting and diarrhea should be evaluated for the presence of these complications. Treatment involves standard measures to correct fluid and electrolyte imbalance. For those seriously ill patients who do not respond to fluid replacement, cardiac monitoring and vasopressors may be required. Those patients with neurologic abnormalities or serious electrolyte imbalance should be observed until these complications resolve.

Chapter 12

RHUBARB and OXALOSIS
(*Rheum* Species)

HISTORY

Although the petioles of rhubarb leaves have been a food source in modern times, the dried root or rhizome has been used as a medicinal herb since the third millennium BC. Chinese rhubarb is traditional herb used as a purgative and bacteriocidal agent for dysentery.[1] In the 16th and 17th centuries, Chinese rhubarb was coveted as a medicinal remedy that was superior to European varieties. During this time, Russian sources (the Commerce Collegium in St. Petersburg, the Rhubarb Commission on the Mongolian border) and the British East India Company supplied Europe with large quantities of rhubarb.[2] This popular laxative was the "All Bran of the Age of Reason." Although the Russian explorer, Nikolai Mikhailovich Przheval'skii, obtained rhubarb seeds from the major Chinese production center (Sining) in the late 1800s, European growing conditions could not duplicate the luxuriant growth of rhubarb cultivated in China. In the early 1900s, the anthraquinone compounds responsible for the purgative action of rhubarb were separated from powdered rhubarb root at the Wellcome Research Laboratories (Beckenham, Kent, UK). Consumption of rhubarb leaves as a food substitute for spinach was encouraged in England during World War I until several deaths were attributed to the ingestion of cooked leaves.[3]

BOTANICAL DESCRIPTION

Species in the oxalate-containing genus *Rheum* include *Rheum officinale* Baillon (Chinese rhubarb), *Rheum palmatum* L. (Turkey rhubarb), *Rheum rhabarbarum* L. (garden rhubarb), and *Rheum rhaponticum* L. (false rhubarb). Other plant species that contain substantial quantities of oxalate include *Halogeton glomeratus* (Bieb.) C. A. Mey. (barilla, saltlover), *Oxalis caerulea* (Small) R. Knuth (blue woodsorrel), *Oxalis corniculata L.* (creeping oxalis, creeping woodsorrel, yellow oxalis), *Portulaca oleracea* L. (common purslane, duckweed), *Rumex acetosa* L. (garden sorrel), *Rumex crispus* L. (curley dock, yellow dock),[4] and *Tetragonia tetragonioides* (Pallas) Kuntze (New Zealand spinach).

Common Name: Garden rhubarb

Scientific Name: *Rheum rhabarbarum* L.

Botanical Family: Polygonaceae (buckwheat)

Physical Description: A garden vegetable plant with large, leathery, heart-shaped leaves and a reddish color.

Distribution and Ecology: *R. rhabarbarum* L. is an introduced, perennial plant that inhabits Alaska, the Rocky Mountain States, Georgia, and the northeastern United States.

EXPOSURE

The leaf petioles (stalks) are used as a vegetable and a constituent of pies. The dried roots have been used medicinally as a cathartic and as a tonic.[5,6] In traditional Chinese medicine, official rhubarb (dahuang) is a purgative and detoxicant used to treat fever, constipation, cancer, abdominal distention and obstruction, jaundice, hematemesis, appendicitis, amenorrhea, skin lesions,

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

food poisoning, inflammation, hypertension, and renal failure.[7,8] The official Chinese herbal medicine contains dried rhizome and root of *R. palmatum* L., *R. tanguticum* Maxim. ex Balf., and *R. officinale* Baillon. The Japanese version of Rhei Rhizoma (rhubarb) also contains *R. coreanum* Nakai.

PRINCIPAL TOXINS

Structure and Properties

Salts of oxalic acid are the main toxic constituents in rhubarb. This chemical is the simplest dicarboxylic acid [$(COOH)_2$] and oxalic acid forms soluble (iron, lithium, potassium, sodium) and insoluble (calcium, magnesium) salts. Boiling spinach for 1 minute removes only about 10% of the insoluble oxalate salts compared with 47% of the soluble oxalate salts.[9] Cooking does not substantially alter the oxalate concentration in rhubarb. Roots of some species of rhubarb (*R. palmatum* L.) contain up to 2% anthraquinone glycoside derivatives similar in structure to the sennosides, which also possess laxative properties.[7] The major active components of the herbs derived from rhubarb (e.g., dahuang) are hydroxyanthraquinone compounds including rhein, emodin, aloe-emodin, and chrysophanol.[10] Figure 12.1 displays the structure of some hydroxyanthraquinone compounds in herbs derived from the Chinese rhubarb (*Rheum officinale*). Emodin is a naturally occurring anthraquinone present in the rhubarb as well as the roots and bark of numerous plants of the genus *Rhamnus* including buckthorn (*Rhamnus cathartica* L.), senna (*Senna alexandrina* Mill.), cascara (*Frangula purshiana* (DC) J.G. Cooper), and aloe (*Aloe ferox* Mill.). This hydroxyanthraquinone compound is a common constituent of herb-based stimulant laxatives that produce mild nephrotoxicity in some rodents following the administration of very high doses (i.e., about 1 g emodin/kg body weight daily for 2 years).[11]

Poisonous Parts

Oxalate occurs in most plant tissues and the amount depends on growing conditions, season, and plant part. The average Western diet contains about 50–150 mg oxalate/d with vegetarian diets somewhat higher (i.e., 150 mg/d).[12] Spinach contains oxalate compounds divided into approximately 55% soluble oxalate and 45% calcium oxalate, whereas rhubarb contains primarily calcium oxalate.[13] The most toxic part of the rhubarb plant is the leaf, which contains <1% fresh weight soluble oxalates.[14] The petioles of rhubarb leaves are edible because of the low oxalate content. Food sources beside rhubarb that contain substantial amounts of oxalate include sugar beets, chocolate, coconut, peanuts, spinach, strawberries, wheat bran, and tea.[15,16] Table 12.1 lists the oxalate content of some common foods. The major bioactive constituents of herbal preparations of rhubarb are phenolic compounds (sennosides, anthraquinone

TABLE 12.1 Oxalate Content of Some Foods

glycosides, glucose gallates, naphthalenes, catechins).[17] These concentrations and types of phenolic compounds (e.g., sennosides, anthraquinone glycosides) vary between different species of *Rheum*.

Mechanism of Toxicity

The ingestion of rhubarb causes oxalate poisoning that is associated with local corrosive effects and renal damage from the excretion of oxalate crystals.[5] The formation of large amounts of calcium oxalate crystals in the body may produce hypocalcemia as well as renal dysfunction, renal calculi, and electrolyte imbalance.[18] The deposition of calcium oxalate crystals in the myocardium of patients with renal failure may occur without the presence of oxalate poisoning.[19] Pathological changes associated with fatal oxalate ingestions include corrosive effects on the gastrointestinal tract, cloudy swelling and hyalin degeneration of the renal tubules, glomerulosclerosis, and birefringent crystals in vascular walls throughout the body.[20]

DOSE RESPONSE

The ingestion of small amounts of plant parts containing oxalates usually causes only mild gastrointestinal irritation. Serious intoxication from the ingestion of rhubarb leaf is not well-documented in the modern medical literature. Fatalities associated with the ingestion of rhubarb probably involved other agents, toxins, or etiologies. The intravenous injection of 20 mg sodium oxalate/kg produced profound hypocalcemia and cardiac arrest.[21]

TOXICOKINETICS

Gastrointestinal absorption of oxalate occurs in the small intestine by active transport and by passive diffusion along the small intestine and the colon. The bioavailability of oxalate is low (<2–6% as total oxalate) and varies with plant species.[15] In a study of volunteers, the average bioavailability of oxalate in sugar beets and spinach was 0.7% and 4.5%, respectively.[22] The mean bioavailability of a solution of sodium (soluble) oxalate in the same study was 6.2%. Endogenous intermediary metabolism in humans produces oxalate as a result of glycine, ascorbic acid, and glycolate metabolism. As end-products of metabolism, oxalates are excreted by the kidney rather than metabolized. Most renal excretion of oxalate absorbed from the diet occurs within 8–12 hours.[13] In a study of 12 volunteers, the elimination half-life of the hydroxyanthraquinone compound, rhein, derived from the Chinese rhubarb was 3.38 ± 0.35 hours.[23]

CLINICAL RESPONSE

Most casual exposures of children to the rhubarb plant produce mild gastrointestinal symptoms (vomiting, diarrhea) that resolve within a few hours.[24] The initial symptoms of oxalate intoxication result from irritation of the oropharynx and the gastrointestinal tract manifest by sore throat, dysphagia, nausea, vomiting, anorexia, diarrhea, abdominal pain, and occasionally hematemesis. Symptoms typically begin within 2–12 hours after ingestion.[14] Serious oxalate toxicity produces renal dysfunction and electrolyte imbalance that develops after signs of gastrointestinal distress. The presence of paresthesias, tetany, hyperreflexia, muscle twitches, and muscle cramps suggest hypocalcemia. Seizures may complicate the clinical course as a result of hypocalcemia.[25] Other sources of oxalosis include excessive oxalate formation as a result pyridoxine deficiency,[26] primary hyperoxaluria with glycolic aciduria or L-glyceric aciduria,[27] increased oxalate intake from the diet, toxins (ethylene glycol, glycolate), renal failure, and fungal infections.[28,29] Rarely, case reports associate exposure to rhubarb with the development of vesiculobullous, photosensitivity dermatitis.[30] Another case report associated acute renal failure, atrophy of the renal tubules, and interstitial renal fibrosis with the chronic ingestion of the nonsteroidal antiinflammatory drug, diclofenac, and a slimming pill that contained anthraquinone derivatives extracted from Rhizoma Rhei (rhubarb).[31]

DIAGNOSTIC TESTING

Analytical Methods

Methods for detecting anthraquinone derivatives in rhubarb include thin layer chromatography,[32] capillary electrophoresis,[33] high performance liquid chromatography (HPLC),[34] high speed counter-current chromatography,[10] high performance liquid chromatography with ultraviolet detection and mass spectrometry,[35] and HPLC coupled with electrospray ionization mass spectrometry.[17] HPLC with mobile phase gradient conditions and UV detection (280 nm) can detect at least 30 compounds in rhubarb at detection limits ranging from 0.05–2 µg/mL.[36] These compounds include anthraquinones, anthraquinone glucosides, dianthrones, phenylbutanones, stilbenes, galloylglucoses, acylglucoses, flavan-3-ols, procyanidins, and gallic acid.

Biomarkers

Normal values of oxalate in the serum range from approximately 60–230 µg/dL.[37] The concentration of urinary oxalate depends on urine volume and electro-

lytes as well as diet. In a study of 20 men with recurrent calcium containing kidney stones, the upper ranges of urine oxalate concentrations for daily urine volumes of 1, 2, and 3 liters were 46 mg, 55 mg, and 63 mg, respectively.[38] Women excreted slightly lower daily amounts of urine oxalate.

Abnormalities

The definition of hyperoxaluria is the urinary excretion of >0.5 mmol oxalate/1.73 m^2 body surface area daily. Electrolyte imbalance (e.g., hypocalcemia) complicates serious cases of oxalate poisoning. Laboratory evidence of renal dysfunction includes the presence of anuria, oliguria, proteinuria, hematuria, and oxaluria. Microscopic examination of urine sediment may demonstrate red blood cells, leukocytes, or birefringent crystals of calcium oxalate as either needle-like or envelope-shaped dimorphic forms.

TREATMENT

Decontamination

Decontamination is not usually necessary following the ingestion of oxalate-containing plant parts. Symptomatic treatment for pharyngeal irritation includes demulcents (milk, chipped ice) and antihistamines. For serious oxalate ingestions, lavage with 0.15% calcium hydroxide (lime water) to precipitate insoluble calcium oxalate in the gastrointestinal tract was a previously recommended treatment for patients presenting to a health care facility within one hour of ingestion, but there are no clinical data to substantiate the efficacy or safety of this therapeutic modality.

Supplemental Care

For symptomatic patients, generous fluid replacement (>2 L/m^2/d) should be administered to promote the excretion of calcium oxalate crystals from the kidney tubules. The treatment of patients with *chronic* secondary oxalosis includes the use of sodium citrate (0.15 g/kg/d) to inhibit calcium oxalate crystallization in the kidneys,[39] but there are few clinical data on the use of sodium citrate following the *acute* ingestion of calcium oxalate-containing plants. Symptomatic patients should receive a complete blood count, serum electrolytes including serum calcium, and kidney function tests (serum creatinine and BUN [blood urea nitrogen], urinalysis). Kidney function may deteriorate over the first week and careful management of fluid and electrolyte balance may be necessary. Intravenous calcium is not usually required to reverse the oxalate-induced hypocalcemia unless the patient is symptomatic. The initial adult treatment for symptomatic hypocalcemia is 10 mL of 10% calcium gluconate intravenously with cardiac monitoring over a 10-minute period and repeated if symptoms, signs, and electrocardiogram (ECG) evidence (e.g., shortened QT interval) persist. Hemodialysis easily removes oxalate from the blood with most elimination within the first 2 hours.[40]

III Microbes

A Bacteria

Chapter 13

BACILLUS CEREUS

CYRUS RANGAN, MD, FAAP

HISTORY

Bacillus cereus Frankland and Frankland (*B. cereus*) is one of over 100 species belonging to the genus *Bacillus*, which contains other foodborne species (*B. anthracis, B. thuringiensis, B. mycoides*, and *B. pseudomycoides*).[1] *B. cereus* is usually a gram-positive aerobic spore-forming bacterium that causes two distinct gastrointestinal illnesses, the emetic syndrome and the diarrheal syndrome. *B. cereus* can become a gram-negative or a facultative anaerobe with age while maintaining toxin-producing properties.[2] In 1955, the first reported cases of *B. cereus*-induced food poisoning occurred in Scandinavia, when four outbreaks involving over 600 patients were linked to consumption of vanilla sauce contaminated by *B. cereus*.[3] Although food poisoning from *B. cereus* is well known, cases are vastly underreported or diagnosed as presumed viral infections, secondary to a short and generally mild course of afebrile gastrointestinal illness that usually resolves spontaneously. Detection of *B. cereus* during food poisoning episodes requires analysis of stool, vomitus, and food specifically for this bacterium. In an outbreak during 1985, 11 of 36 customers of a Japanese restaurant developed acute gastrointestinal symptoms. Stool and vomitus specimens were positive for *B. cereus*, which was also found in hibachi steak served to these patrons.[4] In 1993, 14 of 67 staff and children at two Virginia daycare centers developed gastrointestinal symptoms after consuming a catered lunch from a Chinese restaurant. *B. cereus* was isolated from the vomitus of one child and from leftover chicken fried rice, which was held at room temperature for several hours after initial cooking and reheating.[5]

EXPOSURE

Source

ENVIRONMENT

Bacillus cereus is ubiquitous in water and soil. Uptake of spores and the bacterium by rice plants occurs in rice fields contaminated by *B. cereus*. Transfer of *B. cereus* to food occurs not only from soil and fertilizers during harvesting and postharvest handling, but also from contamination during processing, shipping, and marketing.[6] Although this bacterium frequently contaminates vegetables, the occurrence of diarrheal illness secondary to the ingestion of *B. cereus* is relatively uncommon.

ANIMAL

Bacillus cereus can colonize the gastrointestinal tract of some invertebrates (e.g., worms, flying insect larvae), resulting in the exposure of cows to this bacteria. *B. cereus* spores may contaminate dairy feed and provide a source for the contamination of cow milk by *B. cereus*.[7] The life cycle of this bacterium may contribute to the occurrence of *B. cereus* in the milk from cows and goats.[8] Some humans transiently carry *B. cereus* in the gut without symptoms (14–43%), as a result of the ingestion of nonpathogenic concentrations of the bacterium from food.[9,10]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Food

Bacillus cereus can contaminate most foods, but the development of *Bacillus cereus*-induced food poisoning requires high bacterial counts. Foods frequently associated with high *B. cereus* content include rice (particularly fried rice), cereals, pasta, corn, cornstarch, beef, poultry, pasteurized dairy products,[11] infant formulas, meats, fish, vegetables, and soups.[12,13] The diarrheal type is typically associated with vegetables, sauces, soups, meat, and milk products, whereas the emetic type is usually associated with rice, pasta, noodles, and pastry.[14] Bacterial growth is enhanced in proteinaceous environments. The preparation of fried rice provides an ideal milieu for bacterial growth. Rice is typically cooked in advance, and then cooled at room temperature when spores begin to germinate. Subsequent stir-frying does not generate sufficient heat to destroy toxins formed during the storage of precooked rice. *In vitro* studies indicate that quantities of emetic-type toxin sufficient to cause human illness can form at room temperature (20 °C/68 °F) within 12–16 hours after inoculation of rice with *B. cereus*.[15] These studies also indicate that the addition of vinegar, mayonnaise, or catsup to foods contaminated with *B. cereus* inhibits both bacterial proliferation and toxin formation. When the rice is briefly reheated or flash-fried, the addition of proteinaceous foods (e.g., chicken, beef, eggs) augments the growth of *B. cereus*.[16,17] Although bacterial growth occurs in these proteinaceous foods, experimental studies suggest that the production of emetic-type toxin is relatively low in eggs, milk, and meat compared with rice.[15] Consequently, these proteinaceous foods are a source of contamination for improperly refrigerated rice, but rice remains the most common source for *B. cereus*-associated food poisoning.

Food Processing

Proper refrigeration does not eliminate *B. cereus* because of the ability of these bacteria to survive low temperatures (i.e., 5 °C–8 °C/41 °F–46 °F).[18] These psychrotrophic organisms multiply optimally at 68 °F (20 °C), but these organisms remain viable at temperatures from 32 °F–104 °F (0 °C –40 °C). Accordingly, room temperature (72 °F/22 °C) provides a favorable environment for *B. cereus* growth, while refrigeration (35 °F/2 °C) and reheating do not always inhibit growth or kill these organisms.[19] The US Department of Agriculture and the European Food Safety Authority do not have specific regulations on *B. cereus* in foodstuffs.[20] The ability to control *B. cereus* in commercial food processing is limited by a number of factors including the ubiquity of the organism, the resistances of spores to commercial disinfectant processes, and the lack of easily detectable contamination by smell or sight.[21] Vegetative cells can form films on stainless steel equipment and containers, conferring even higher resistance to disinfectants and heat.[22] Chlorine, chlorine dioxides, and FIT powder (i.e., a combination of glycerin, starch, trisodium phosphate, sodium lauryl sulfate, and grapefruit oil) are effective disinfectants against *B. cereus* vegetative cells and spores.[23] Pasteurization is an effective means of killing vegetative cells, but the pasteurization process does not kill all *B. cereus* spores.[24] Each vegetative cell is capable of producing one spore. The spore core, or protoplast, is surrounded by a cortex and three protein coats that protect the core from environmental stresses, such as heat, radiation, chemical disinfectants, and desiccants.[2] Spores from *B. cereus* withstand high temperatures during cooking and pasteurization, allowing them to germinate as food cools. Therefore, the storage of precooked food for later serving requires immediate refrigeration after cooking to reduce germination of *B. cereus* spores. Food should be reheated at high temperatures (>140 °F/60 °C,) to kill new vegetative cells, and food should be served immediately.[6] Microwave ovens cook food from the outside-in, so a thermometer should be placed into the center of the food to confirm adequate reheating temperatures. Although proper reheating can kill vegetative cells, the spores and preformed toxins can survive normal food preparation methods.[25] Use of separate utensils and containers for cooked and uncooked food may help prevent recontamination of cooked food, and food handlers must practice strict personal hygiene and receive proper food safety training.[26,27]

TOXINS

Physiochemical Properties

Distinct toxins are responsible for two forms of gastrointestinal illness caused by *B. cereus*. The emetic-type of illness results from the formation of the dodecadepsipeptide toxin, cereulide, whereas the diarrheal form of the illness probably involves several enterotoxins.[28]

Emetic Toxin

Cereulide is a preformed, 1165-Da cyclic dodecadepsipeptide that is heat stable to 259 °F (126 °C).[29] The production of cereulide by *B. cereus* depends on several factors including the type of the food, temperature, pH, preparation methods (e.g., aeration), and the specific strain of *B. cereus*.[30,31] The chemical structure of cereulide includes a ring-shaped structure consisting of three repeats of a four-amino acid sequence (leucine,

alanine, valine, valine). Cereulide is chemically related to valinomycin, a potassium-selective ionophore antibiotic produced by *Streptomyces fulvissimus* (Jensen) Waksman and Henrici. *S. fulvissimus* is a filamentous or rod-shaped microorganism of the order *Actinomycetales*, which also occurs in soil.[32] Cereulide is resistant to pepsin and stable in the pH range between 2 and 11. This latter property accounts for the ability of cereulide to resist degradation in the human stomach.[33]

Diarrheal Toxin

Bacillus cereus produces at least four heat-labile enterotoxins capable of producing diarrheal illness. These enterotoxins include two protein complexes (hemolysin BL, nonhemolytic enterotoxin) and two enterotoxic proteins (enterotoxin T, cytotoxin K).[34] Hemolysin BL (HBL), the diarrheal toxin, is a 40-kDa, three-component protein that is heat labile and pH stable between 4 and 11.[35] A minority of *B. cereus* strains produce a nonhemolytic enterotoxin (Nhe) that also causes the diarrheal syndrome.[36] The hemolytic notation of HBL refers to the hemolysis induced by this toxin in sheep red blood cells *in vitro*; however, there is no direct evidence of a similar effect in humans.[37] Whether a particular strain of *B. cereus* will elaborate cereulide or HBL depends in part on the following flagellar (H) serotype: cereulide production, types 1, 5, 8, 12, and 19; HBL production, types 1, 2, 3, 8, 10, 12, and 19. Although some *B. cereus* strains are capable of producing both toxins, only one toxin is usually elaborated in disease states.[1] Some strains of *Bacillus* species other than *B. cereus* can produce emetic toxins or enterotoxins including *B. subtilis*, *B. mojavensis*, *B. pumilus*, and *B. fusiformis*.[38]

Mechanism of Toxicity

Both spores and vegetative cells are found in many foods. Cooking destroys vegetative cells, but spores survive to germinate when food is cooled to room temperature. Emetic (cereulide) or diarrheal (HBL) enterotoxins are subsequently elaborated when food is improperly stored and reheating fails to destroy these toxins. Following ingestion, these enterotoxins produce either the emetic syndrome or the diarrheal syndrome. The mechanism and site of action of cereulide is unknown. High biliary concentrations of cereulide suggest that this compound undergoes enterohepatic recirculation. Rapid onset of illness and the lack of a diarrheal component suggest that the stomach is the site of action.[39] Animal studies indicate that cereulide disrupts mitochondrial membrane potential and impairs mitochondrial fatty acid metabolism, resulting in a dose-dependent increase of small fatty droplets and massive degeneration of hepatocytes following high doses.

Hemolysin BL consists of three polypeptide components: B, L_1, and L_2. The B component forms pores in cell membranes of the intestinal mucosa, allowing the L_1 and L_2 components to lyse cells and activate adenylate cyclase, resulting in altered tissue permeability, tissue damage, and fluid secretion.[40] *B. cereus* also produces a series of phospholipases that have an affinity for phosphatidylcholine and sphingomyelinase on intestinal cell membranes.[41] These enzymes play a role in mucosal tissue degradation, and are structurally similar to alpha-toxin produced by *Clostridium perfringens*.[42]

DOSE RESPONSE

The bacterial dose required for the development of the emetic syndrome has not been established because the number of bacteria required to produce sufficient preformed toxin to cause symptoms is not known. Animal studies suggest 9–12.9 µg/kg of cereulide enterotoxin are required to induce emesis.[43,44] The bacterial dose for the diarrheal syndrome is accepted as $>10^5$ CFU/g of food substance. This dose is based on epidemiological calculations of data obtained from confirmed *B. cereus* outbreaks with diarrheal syndrome (range: 5×10^4–10^{11} CFU/g of food substance).[45]

CLINICAL RESPONSE

Bacillus cereus causes the following two forms of food poisoning: a heat-stable toxin-induced emetic form that is similar to *Staphylococcus aureus* food poisoning, and heat-labile enterotoxin-induced diarrheal form that produces symptoms similar to *Clostridium perfringens* food poisoning. Nausea, abdominal cramping, bloating, and vomiting characterize the emetic syndrome. Symptoms occur 30 minutes to 6 hours after ingestion and resolve within 6–24 hours.[1] Mild diarrhea is occasionally associated with the emetic form of gastrointestinal illness. The diarrheal syndrome is characterized by mild nausea, occasional vomiting, tenesmus, and profuse, nonbloody diarrhea. Symptoms occur 8–16 hours after ingestion and persist 12–24 hours. Case series suggest that prolonged diarrhea occasionally occurs after *B. cereus* infections. In a 1993 case series of 139 reports of *B. cereus*-induced diarrheal disease, 34% of patients developed diarrhea outside of the usual range of 6–24 hours, and 23% of patients reported fever based on a postoutbreak survey.[46] Death from either syndrome is extremely rare, and person-to-person spread does not occur.

Rarely, case reports document the development of serious extra gastrointestinal infections caused by *B. cereus*, including meningitis in an immunocompromised

patient,[47] sepsis in children with acute leukemia,[48] bacteremia in neonates,[49] and fulminant necrotizing fascitis in a healthy child following a puncture wound from a tree branch.[50] A case report associated the development of fulminant liver failure and rhabdomyolysis in a 17-year-old boy with high concentrations of *B. cereus* emetic toxin (cereulide).[51] Postmortem examination of other fatal cases of *B. cereus* poisoning demonstrated liver steatosis,[52] but these patients did not develop fulminant hepatic failure and the cause of this abnormality remains unclear. Postmortem examination of this boy revealed a diffuse microvesicular steatosis and midzonal necrosis, consistent with impaired β-oxidation of liver mitochondria. The differential diagnosis for microvesicular steatosis includes hypoglycin (ackee fruit, renta yams), neem (margosa) oil, aflatoxin, valproic acid, aspirin, tetracycline, dideoxynucleoside drugs (zidovudine, didanosine, lamivudine), fialuridine, fatty liver of pregnancy, and Reye's syndrome.

DIAGNOSTIC TESTING

Analytical Methods

In the healthcare setting, routine analytical testing for *B. cereus* or the associated toxins is not clinically useful, as symptoms are self-limited and short in duration. Official methods of analysis are available from AOAC International (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) for the enumeration and confirmation of *Bacillus cereus* in foods[53] and for the differentiation of members of the *Bacillus cereus* group.[54] In epidemiological studies, isolation of *B. cereus* bacteria from stool, vomit, or leftover food is performed on mannitol-egg yolk-polymyxin agar, followed by serotyping of vegetative cells.[55] Because asymptomatic people can transiently shed *B. cereus*, simple identification in clinical specimens is not sufficient to confirm *B. cereus* foodborne poisoning unless both clinical and food specimens contain $>10^5$ CFU/g of an identical serotype.[56] Food sampling in outbreaks is performed on representative samples of 50 grams each on different parts of the food in question. If transport of food to a laboratory is necessary, raw or cooked food should be packed in insulated containers at temperatures ≥42 °F (≥5 °C).[57] Dried food may be transported without refrigeration. Three methods for the detection of emetic toxin include cytotoxicity assay, high performance liquid chromatography (HPLC) with ion trap mass spectrometry, and a sperm-based bioassay.[14] Cereulide enterotoxin is identified by a HEp-2 vacuolization assay, in which the toxin uncouples oxidative phosphorylation in HEp-2 mitochondria. Visualization of mitochondrial swelling and measurement of oxygen utilization indicates a positive test for cereulide. Methods for confirmation and quantitation of cereulide involve HPLC with ion trap mass spectrometry.[58] The limit of detection with this method was 10 pg cereulide per injection. Parts of the tripartite hemolysin BL enterotoxin can be identified via latex agglutination assay and immunoassay, but these tests are limited by their inability to identify the component B, L_1, and L_2 peptides simultaneously. All three components are necessary for HBL to be bioactive.[59] Hemolysin BL and cereulide can also be confirmed using ileal loop assays in rhesus monkeys and rabbits, but these tests are labor-intensive and expensive. Consequently, these tests are reserved for epidemiologic studies of outbreak that require definite identification.

Biomarkers

Postmortem analysis of a case associated with cereulide toxicity and fatal fulminant hepatic failure demonstrated the accumulation of cereulide in the small intestine, liver, and bile as well as in a cooking pan used by the patient.[60] Hemolysin has been identified only in fecal specimens from cases of foodborne poisoning associated with *B. cereus*.

Abnormalities

Both the emetic syndrome and the diarrheal syndrome can produce severe serum electrolyte abnormalities, with a profile similar to that seen in dehydration from gastrointestinal fluid losses. Severe dehydration involves hypernatremia (serum Na >150 mEq/L) or hyponatremia (serum Na <130 mEq/L); hypokalemia (serum K <3.0 mEq/L); hypochloremia, and elevated urine specific gravity (SpG >1.020). Low serum bicarbonate results from lactic acid production or elevated bicarbonate secondary to contraction alkalosis. The short duration of illness limits the severity of fluid and electrolyte imbalances, which usually resolve spontaneously.[61]

TREATMENT

Treatment includes rehydration and bowel rest for both the emetic and the diarrheal syndromes. Oral rehydration is usually sufficient, but intravenous fluid replacement and hospitalization may be necessary in cases of severe dehydration or severe electrolyte abnormalities, particularly in young children or elderly patients.[62,63] Anti-emetics may alleviate symptoms in the emetic syndrome. Antimotility agents (e.g., loperamide, diphenoxylate) may curtail symptoms in the diarrheal syndrome, but these agents should be administered cautiously. The short duration of both syndromes generally limits the

necessity of these medications. There are no clinical trials that demonstrate an improvement in clinical outcome, avoidance of hospitalization, or shortened duration of symptoms following the use of either antiemetics or antidiarrheal agents. *B. cereus* produces beta-lactamases, generating resistance to penicillins and cephalosporins, but *B. cereus* is usually susceptible to aminoglycosides, sulfonamides, vancomycin, erythromycin, tetracycline, ciprofloxacin, and clindamycin.[64,65] Although antimicrobials are beneficial in extra gastrointestinal infections of *B. cereus* (e.g., septicemia, endophthalmitis, keratitis, endocarditis, meningitis, pneumonia, wound infections), they are not routinely used in cases of *B. cereus* foodborne poisoning, even when symptoms are prolonged.

Chapter 14

CAMPYLOBACTER JEJUNI

Cyrus Rangan, MD, FAAP

HISTORY

Campylobacter jejuni (Jones et al.) Véron and Chatelain (*C. jejuni*) is a gram-negative, catalase-positive, oxidase-positive, nitrate-positive, S-shaped, flagellated, motile rod that was first identified by Theodor Escherich in 1886 as a rare cause of infant cholera in Germany.[1] Until case reports of *Campylobacter* bacteremia in humans in the 1950s, *Campylobacter* was considered an animal pathogen.[2] Originally, *Campylobacter* species were categorized as a *Vibrio* species;[3] however, *Campylobacter* became a unique genus in the 1970s following the discovery that multiplication of these bacteria required a microaerophilic (5% oxygen) environment and these bacteria could not metabolize carbohydrates or lipids.[4] In the 1970s, *Campylobacter* was recognized as a common cause of human gastroenteritis.[5] Although numerous other species in Campylobacteraceae have been implicated in gastroenteritis (e.g., *C. upsaliensis*, *C. lari*, *C. hyointestinalis* subsp. *hyointestinalis*, *C. coli*), *C. jejuni* causes over 90% of reported cases.[6] *C. jejuni* is the most commonly reported cause of bacterial gastroenteritis in the United States, with an estimated 2 million cases per year in the United States and 4 million cases per year worldwide.[7] *C. jejuni* is a frequent cause of traveler's diarrhea.[8]

EXPOSURE

Source

Environment

Water runoff containing animal feces can contaminate nonchlorinated water sources (e.g., streams and ponds) with *C. jejuni*.[9] This organism can survive for extended periods in still waters by living inside waterborne protozoa.[10]

Animal

Healthy humans do not carry *C. jejuni*, but a variety of animals are carriers of *C. jejuni* including asymptomatic wild animals (water fowl, rodents, flying insects),[11] food animals (poultry, cattle),[12] and domestic animals (dogs, cats, birds).[13] *C. jejuni* is commensal in healthy cattle, particularly during the summer. Healthy rodents frequently excrete *Campylobacter* species in their stool including *C. jejuni*.[14] *C. jejuni* thrives at 37 °C–42 °C (99 °F–108 °F), and therefore an optimal reservoir for this bacterium is the chicken, which has a mean body temperature of 41 °C (106 °F).[15] Shellfish caught in contaminated waters may also carry *C. jejuni*.[16] Contact with live animals colonized with *C. jejuni* is a well-documented source of human exposure, especially in young children.[17]

Food

Raw milk, untreated drinking water, and undercooked meat (e.g., chicken) are the most common sources of foodborne illness in humans.[18,19] Undercooked pork, beef, and sausages are also documented food sources.[20] *C. jejuni* frequently contaminates raw chicken. Surveys of retail chickens demonstrate 20–100% contamination rates by *C. jejuni*.[21] *C. jejuni* does not proliferate in food when the ambient temperature is below 37 °C (99 °F) or when ambient oxygen is present at atmospheric conditions. Thus, human infections are sporadic, rarely resulting in outbreaks.[22]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Food Processing

Pasteurizing milk and chlorinating drinking water control *C. jejuni* growth.[23] Proper food handling during preparation and cooking food to >170 °C (338 °F) effectively eliminate *C. jejuni* from consumer products.[24] Screening and isolation of *C. jejuni* in food processing is difficult because the bacteria are usually present in relatively low numbers.

TOXINS

Physiochemical Properties

Campylobacter jejuni proliferates at temperatures from 37 °C–42 °C (99 °F–108 °F).[25] *In vitro* studies indicate that growth and chemotaxis of *Campylobacter* strains are greater at 37 °C (98.6 °F) than at 42 °C (107.6 °F), and these properties suggest that the physiological temperature of humans (37.0 °C/98.6 °F) is potentially more favorable for the expression of virulence than for birds (body temperature, 42.0 °C/107.6 °F).[26] *C. jejuni* is microaerophilic, requiring 3–5% oxygen and 2–10% carbon dioxide for optimal growth.[27] *C. jejuni* is relatively fragile, and these bacteria are sensitive to numerous environmental stresses, including 21% atmospheric oxygen, drying, freezing, heating, disinfectants, and pH < 5.[28] Survival of *C. jejuni* outside the gut is relatively poor, secondary to aerobic stress induced by ambient oxygen concentrations (i.e., 21% oxygen). However, the production of iron-regulated alkyl hydroperoxide reductase (*AhpC*)[29] and a superoxide dismutase (*SodB*)[30] by *C. jejuni* provides some protection from stressful oxidative and aerobic conditions. When stressed, *C. jejuni* absorbs amino acids rapidly from its environment and assumes a dormant coccoidal form, limiting its ability to grow while maintaining its outer membrane. In this state, the organism remains intact, but this form does not grow in these conditions or in culture media. This unique state of *Campylobacter* is known as viable-but-not-culturable (VNC).[31] Once exposed to a microaerophilic environment, VNC organisms resume growth.[32] *C. jejuni* is a highly motile organism with a characteristic S-shape and polar flagella. These organisms do not metabolize lipids or oxidize carbohydrates.[33] Isolation of antimicrobial-resistant *C. jejuni* has evolved concurrently with the administration of ciprofloxacin and enrofloxacin to farm chickens. Since 1995 when the use of quinolones in poultry farms began, human cases of resistant campylobacteriosis have increased annually.[34] Developing countries have higher rates of antimicrobial-resistant *C. jejuni* compared with more developed countries.[35] Antibiotic-resistant isolates demonstrate a genetic mutation that may additionally confer improved fitness for survival because rates of quinolone-resistant strains outpace rates of nonresistant bacteria in food animals, even when antibiotics are not administered.[36]

Mechanism of Toxicity

Darting, corkscrew-like motility allows *C. jejuni* to pass through the acid milieu of the stomach and to colonize the colon and distal ileum.[37] Conditions of decreased gastric acidity enhance survivability of *C. jejuni*.[38] Chemotaxis, adherence to mucosa, and invasion of *C. jejuni* into mucosal cells are mediated by flagella[39] and two cell surface proteins, CadF and PEB1.[40] *Campylobacter* possesses lipopolysaccharide and lipo-oligosaccharide endotoxins, which enhance adherence, increase invasiveness, and improve survival in human serum during bacteremia.[41] *C. jejuni* is vacuolized by intestinal epithelial cells. During vacuolization, *C. jejuni* resists lysosomal degradation via catalase production and anti-oxidant activities of *AhpC* and *SodB*.[42] *C. jejuni* then translocates to the basolateral surface of the epithelial cell and undergoes exocytosis.[43] Subsequently, *C. jejuni* proliferates in the lamina propria and mesenteric lymph nodes, resulting in dissemination and extraintestinal infections (e.g., sepsis, meningitis, mesenteric adenitis).[44] Destruction of intestinal epithelial cells is provoked by a heat-labile, cytolethal-distending toxin composed of three subunits: A, B, and C. Cytolethal-distending toxin subunit B attacks intestinal endothelial cell DNA, and recruits protein kinases to block cells from entering into mitosis.[45] *C. jejuni* induces a local inflammatory reaction mediated by interleukin-8, leukotriene B4, prostaglandin E2, and cyclic AMP. Endothelial cells die, resulting in watery or bloody diarrhea with fecal leukocytes.[46] Guillain-Barré syndrome, an acute autoimmune demyelinating disease of peripheral nerve bundles, is a sequela of *C. jejuni* infection mediated by antigenic similarities between the terminal tetrasaccharide of the *C. jejuni* lipo-oligosaccharide endotoxin and the GM_1 ganglioside on the membrane of peripheral nerves.[47,48]

DOSE RESPONSE

Human feeding studies suggest that 800 *C. jejuni* organisms are required to cause illness in healthy individuals, whereas 400–500 bacteria may cause illness in more susceptible individuals (e.g., young children, elderly individuals, immunocompromised patients).[49,50] Approximately 200 annual fatalities occur in the United States as a result of *C. jejuni* infections, primarily from septicemia in immunocompromised patients.[51] The severity of the infection depends on the strain of *C. jejuni* as well as host characteristics.[52,53] Watery diarrhea typically

occurs in individuals in developing countries following *C. jejuni* infection, whereas individuals in developed countries usually have bloody diarrhea with fever. This dichotomy results from increased immunity in individuals in developing countries secondary to repeated exposures to *C. jejuni* during childhood and throughout life. When infected in developing countries, travelers acquire symptoms that are similar to symptoms observed in their countries of origin.[54]

CLINICAL RESPONSE

Course

Symptoms of *C. jejuni*-induced gastroenteritis include watery or bloody diarrhea, cramps, nausea, myalgias, and fever, similar to the clinical responses to *Shigella* spp., *Salmonella* spp., enteroinvasive *Escherichia coli, E. coli* 0157:H7, *Yersinia enterocolitica*, and *Vibrio parahaemolyticus*.[51] In a study of 877 episodes of bloody diarrhea (>3 stools over 24 hours) presenting to a US emergency department, 168 enteropathogens (30.6% of stools samples) were identified.[55] The most common pathogens were *Shigella* spp. (15.3%), *Campylobacter* spp. (6.2%), *Salmonella* spp. (5.8%), and Shiga toxin-producing *E. coli* (2.6%). Abdominal pain, fever, headache, lethargy, and anorexia may precede diarrhea for several hours. Tenderness to palpation in the right lower quadrant may accompany abdominal pain, resulting in a clinical picture that mimics appendicitis before the onset of diarrhea.[56] Appearance of blood in stools may be occult or grossly bloody.[57] Incubation time is approximately 2–5 days after exposure.[58] Symptoms typically resolve within 3–10 days after the onset of illness, with recrudescence in approximately 25% of untreated cases.[58] Diarrhea persists for 1–2 weeks in 20–30% of cases, and longer than 2 weeks in about 5–10% of cases.[58] Adults may have severe inflammatory diarrhea, resembling Crohn's disease, ulcerative colitis, or pseudomembranous enterocolitis.[51] Young children usually have frequent, watery, secretory diarrhea, often without blood.[59] *Campylobacter*-induced abdominal pain and tenderness with bloody diarrhea in young infants may mimic intussusception.[56]

The annual incidence of *C. jejuni* infections in infants in the US population is approximately 14 per 100,000.[60] This rate decreases to 4/100,000 during adolescence, but annual incidence increases to 8/100,000 in young adults. Older adults incur the illness at a rate of 3/100,000. Population susceptibility and low threshold for seeking medical attention cause the higher disease rate in infants; poor dietary and food-handling practices cause the upswing during young adulthood. Breast-fed infants have lower rates of infection with *C. jejuni* than bottle-fed infants. However, the incidence of this illness in infants increases after weaning.[61]

Complications

Transient bacteremia is relatively common, but severe complications (e.g., septic shock, meningitis, urinary tract infection, cholecystitis) occur in <0.1% of reported cases of campylobacteriosis, most commonly in elderly and in immunocompromised patients.[51] *C. jejuni*-induced septic abortion is a rare complication.[62] The human fatality rate from *C. jejuni* infection is less than 0.1%, and occurs primarily from sepsis in immunocompromised patients.[51] Prominent postinfectious manifestations include reactive arthritis and Guillain-Barré syndrome. Reactive arthritis occurs in 1% of *Campylobacter* cases, typically 7–10 days after the onset of diarrhea. Symptoms of this reactive arthritis are usually monoarticular and confined to the knee, but inflammation may involve any large joint.[63] The appearance of reactive arthritis has a 60% association with human lymphocyte antigen B27 (HLA-B27).[64] However, there is some variation in the association between spondyloarthropathies and various HLA-B27 subtypes (e.g., HLA-B*2706 among Southeast Asian populations and HLA-B*2709 among Sardinians lack an association).[65] Guillain-Barré syndrome is an autoimmune disorder with ascending paralysis and respiratory failure. Some patients demonstrate the Miller-Fisher variant, accompanied by ophthalmoplegia, areflexia, and cerebellar ataxia.[66] One in 3,000 cases of *C. jejuni* is associated with Guillain-Barré syndrome, and *C. jejuni* may be responsible for up to 40% of all Guillain-Barré syndrome cases.[67] *Campylobacter*-associated Guillain-Barré syndrome is frequently very severe with a 20% rate of residual disabilities and a 2–3% mortality rate.[68] Rare postinfectious sequelae of *C. jejuni* infection include infectious myocarditis,[69] erythema nodosum, IgA-nephropathy, and hemolytic-uremic syndrome.[70]

DIAGNOSTIC TESTING

Analytical Methods

Phase-contrast microscopy and darkfield microscopy demonstrates S-shaped organisms with darting, corkscrew-like motility.[37] Gram stain reveals thin, curved, gram-negative rods that are difficult to distinguish from *Vibrio* spp.[71] Direct plating of stool specimens is an inexpensive method to culture *C. jejuni*, but sensitivity is relatively low due to increased prevalence of VNC or stressed organisms with exposure to atmospheric oxygen.[32] Under aerobic conditions, *C. jejuni* remains intact, but these organisms are unable to grow

in culture. Specimens may be pre-enriched to decrease the prevalence of VNC organisms by raising ambient temperature to 37 °C–42 °C (99 °F–108 °F).[72] Isolation requires an antibiotic-containing enrichment broth, special antibiotic-containing agar plates (i.e., Campy-BAP, containing vancomycin, trimethoprim, and polymyxin), and a microaerophilic atmosphere with 5% oxygen and an elevated concentration of carbon dioxide (10%).[73] These conditions are necessary to reduce the growth of competing organisms. Because of these requirements, most clinical laboratories do not routinely isolate *Campylobacter* species, and the isolation of these organisms occurs only after specific requests. These methods require several days to a week to complete. Stool specimens should be submitted for culture in refrigerated, airtight containers to minimize contact with atmospheric oxygen.[74] Rectal swabs in bacteria transport media are also adequate. Stools may remain positive for *C. jejuni* for several weeks with or without antimicrobial therapy.[75]

The identity of *C. jejuni* isolates are confirmed by phenotyping or latex-agglutination.[76] Enzyme-linked immunosorbent assay (ELISA) detects *C. jejuni* with 96% sensitivity and 99% specificity.[77] Hybrid polymerase chain reaction (PCR)-ELISA assay is the most rapid (<24 hours) method to identify *C. jejuni* with high (99.7%) sensitivity and specificity (99%).[78,79] Serologic methods are available, but these methods are reserved for epidemiological investigations of outbreaks rather than clinical management.[80] There are no official AOAC International (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) methods for the detection of *Campylobacter* species in food.

Biomarkers

Bacteremia is confirmed by positive routine culture for *Campylobacter* species in blood samples. Routine analytical methods are not available for the detection of the toxins associated with *C. jejuni*.

Abnormalities

Stools frequently contain gross or occult blood. Light microscopy reveals fecal leukocytes in approximately 75% of cases.[81] Complete blood count typically reveals a normal white blood cell count, occasionally with a left shift; however, the white blood cell count is usually elevated in *Campylobacter* septicemia.[51] Mild elevations in erythrocyte sedimentation rate, C-reactive protein, and alanine aminotransferase are often observed in patients with reactive arthritis, Reiter syndrome, and Guillain-Barré syndrome.[25] Severe dehydration involves hypernatremia (Na > 150 mEq/L) or hyponatremia (Na < 130 mEq/L); hypokalemia (K < 3.0 mEq/L); hypochloremia, or elevated urine specific gravity (SpG > 1.020). Low serum bicarbonate results from lactic acid production or elevated bicarbonate secondary to contraction alkalosis.

TREATMENT

Treatment primarily involves bowel rest and fluid and electrolyte replacement. Oral rehydration is usually sufficient, but intravenous fluid replacement and hospitalization may be necessary in cases of severe dehydration, severe electrolyte abnormalities, or severe anemia and blood loss, particularly in young children or elderly patients.[82,83] Most *C. jejuni* infections are self-limited, and consequently the treatment of *C. jejuni* infections with antibiotics is appropriate only in selected cases. Early antimicrobial treatment may benefit patients with persistent fevers, bloody diarrhea, or more than eight stools per 24-hour period; patients with symptoms persisting for more than one week; pregnant patients; and immunocompromised patients.[84] *C. jejuni* demonstrates high rates of resistance to penicillins, most cephalosporins, tetracycline, and metronidazole.[85] Treatment with erythromycin for 5–7 days reduces illness duration by 5–10 days and attenuates subsequent fecal shedding of bacteria. Mild resistance to macrolide antibiotics exists, and the resistance to newer (e.g., azithromycin, clarithromycin) and to older (e.g., erythromycin) macrolide antibiotics is similar.[86,87] Antimicrobials are most beneficial when administered early in the course of illness. However, antimicrobial therapy typically begins after the return of *C. jejuni*-positive stool cultures, thus limiting the practical benefit of antimicrobial therapy in *C. jejuni* infections.[88] *C. jejuni* exhibits a significant rate of resistance to quinolones, especially in populations of developing countries.[89] Resistance may prolong illness and increase the severity of infection, especially in bacteremic patients, and the use of quinolones in susceptible strains may enhance the survival of the organism.

Loperamide may reduce the severity of symptoms in adult patients, but antidiarrheal agents theoretically increase the risk of systemic bacterial invasion when used alone. Therefore, loperamide is recommended only with concurrent administration of an antibiotic.[90] Patients with sepsis, meningitis, or other severe systemic infections should be treated intravenously with a third-generation cephalosporin and gentamicin, pending laboratory results of antimicrobial susceptibilities.[91] Patients with Guillain-Barré syndrome require intensive care monitoring, and should be observed closely for the development of respiratory failure. Some Guillain-Barré syndrome patients benefit from the administra-

tion of intravenous immunoglobulin or plasmapheresis. Survivors of Guillain-Barré syndrome may require long-term physical therapy and rehabilitation.[92]

Chapter 15

CLOSTRIDIUM BOTULINUM (Botulism)

Cyrus Rangan, MD, FAAP

HISTORY

Clostridium botulinum (van Ermengem) Bergey et al. (*C. botulinum*) is a gram-positive, anaerobic, spore-forming, motile bacillus. The German physician, Justinus Kerner, first described botulism (botulus [*Latin*]: "sausage") in 1817, when 230 Germans fell ill from eating home-fermented blood sausage.[1] Belgian bacteriologist Emile Pierre van Ermengem isolated *C. botulinum* in 1895 after he traced an outbreak of botulism to smoked ham consumed at a local funeral.[2] American biochemist Edward J. Schantz isolated botulinum neurotoxin in 1944.[3] In the United States each year, the Centers for Disease Control (CDC) report approximately 100 cases of botulism (0.1 per 1 million people) divided into the following categories: infant botulism, 72% (50–60% in the state of California); foodborne botulism, 25%; and wound botulism, 3%. The botulism fatality rate dropped from 60% (1899–1949) to 15.5% (1950–1996), primarily as a result of early clinical recognition and advances in treatment. Since the 1990s, mortality has been <2% for all toxin types.[4]

Since September 11, 2001, public health programs have raised awareness for terrorism-associated releases of botulinum toxin into food, water supplies, and air.[5] The Japanese, Soviet, British, Canadian, and American militaries investigated botulinum toxin as a biologic agent beginning in World War II. The infamous Japanese Unit 731 fed botulinum toxin to prisoners in Manchuria during experiments with this potential biological agent.[6] The Soviets exposed animals to botulinum toxin during experiments on Vozrozhdeiye Island in the Aral Sea. In the early 1990s, the Japanese cult, Aum Shinrikyo, released a *C. botulinum* preparation in Japan, but the attempt was unsuccessful. Prior to the first Gulf War, botulinum toxin was the main weaponizable biological agent in the Iraqi arsenal.[7]

EXPOSURE

Source

Botulinum toxin is produced by all strains of *Clostridium botulinum* and certain strains of three other *Clostridia* species (*C. argentinense* Suen, *C. baratii* corrig. (Prévot) Holdeman and Moore, and *C. butyricum* Prazmowski). For practical purposes, all of these toxin-producing strains are referenced under the single heading of *C. botulinum*, and designated by seven distinct neurotoxin serotypes (A–G). Although the neurotoxins of these seven types are structurally different, these neurotoxins all produce similar clinical effects. All of these species are associated with human disease except *C. argentinense*, which causes neurotoxicity only in animals. Strains of *C. botulinum* produce one and occasionally two of the seven types of neurotoxins.

Environment and Distribution

Clostridium botulinum is found worldwide in soil and in both freshwater and saltwater aquatic sediments, where dormant spores remain viable for several years.[8] Windy conditions and disturbed soils (e.g., construction sites) increase the risk of exposure to *C. botulinum*.[9] Vacuum

cleaners may emit or resuspend botulinum spores into indoor air spaces, but the clinical significance of this exposure is unclear.[10,11] Human cases are caused primarily by *C. botulinum* types A, B, and E. Type A accounts for 86% of *C. botulinum* cases west of the Mississippi River; whereas type B accounts for 60% of *C. botulinum* cases east of the Mississippi River.[4] Type E causes 25% of foodborne botulism cases and 16% of all botulism cases in the United States, primarily in Alaska and the Great Lakes.[12] *C. botulinum* types C and D cause botulism in animals. *C. botulinum* type F is a rare cause of foodborne and infant botulism.[13,14] *C. botulinum* type G has been implicated, but not confirmed as a cause of sporadic deaths in Argentina and Switzerland.[15]

Animal

The feces of asymptomatic grazing animals may harbor *C. botulinum* spores.[16,17] *C. botulinum* type *E* is found naturally in marine life in colder climates.[18,19] Fermented preparations of beaver, fish heads, fish eggs, whale, and seal have been associated with botulism,[20] but the potential for the introduction of this bacterium during the food preparation process limits conclusions regarding the source of the botulism.

Food

Home-preserved or home-fermented vegetables, fruits, and canned meats account for 65% of reported foodborne cases of botulism.[12] Commercial foods account for approximately 7% of foodborne cases. About 18% of foodborne cases do not have a traceable food source. The traceable sources in most US outbreak investigations are stored vegetables, such as asparagus, beets, carrots, carrot juice, corn, green beans, and mushrooms.[12] Canned fruits, corn syrup, and honey harbor significantly fewer vegetative bacterial cells and less botulinum toxin because *C. botulinum* grows more slowly in high-sugar environments; however, 15% to 25% of honey products harbor high counts of botulinum spores (especially type B).[21] Spores may germinate readily in the relatively alkaline and low oxygen environment in the gastrointestinal system of an infant.[22] The source of the inoculum is unknown in approximately 85% of cases of infant botulism with the ingestion of honey confirmed in only 15% of cases.[4] The CDC recommends that honey not be given to infants younger than 12 months old. Improperly prepared home-canned baby food is a potential source of botulism in older infants.[23] The source of botulism is frequently unknown in breastfed children <2 months of age, and predisposing factors (e.g., constipation, preexisting intestinal flora, acidic food) may be more important than food sources.[24] A bulging or dented container may indicate gas production from *C. botulinum* in canned foods.[12,25] Since 1950, sporadic outbreaks of botulism have been traced to fried onions,[26] venison jerky,[27] poultry stuffing, baked potatoes,[28] potato salad,[29] hash browns,[30] hazelnut yogurt,[31] home-prepared fermented tofu,[32] and garlic-in-oil infusions.[33]

Medical

BOTOX® (Allergan Inc., Irvine, CA) is a crystalline botulinum toxin type A formulated for cosmetic purposes, such as the treatment of strabismus, blepharospasm, glabellar lines, primary axillary hyperhidrosis, and cervical dystonia. Myobloc® and Neurobloc® (Solstice Neuroscience, Malvern, PA) contain botulinum toxin B that is approved for the treatment of cervical dystonia.

Food Processing

Clostridium botulinum growth can be controlled by high acidity, high salinity, high concentration of dissolved sugar, high oxygen concentrations, low moisture, and the use of preservatives.[34] Canned vegetables are low acid foods that may not be sufficiently heated to kill spores, resulting in an oxygen-poor medium that allows botulinum spores to germinate and to produce botulinum toxin. Pressure canners can be used; 0.2 M salt solutions and preservatives may be added to home-canned vegetables to prevent *C. botulinum* growth. Canned tomatoes and tomato sauce produce sufficient acid to prevent growth. The US Food and Drug Administration (FDA) requires all commercially canned foods to undergo cooking at 121 °C under pressure for 3 minutes.[35] All home-canned foods should be boiled for at least 20 minutes before serving to eliminate the heat-labile, preformed botulinum toxin.[36] Nitrates and nitrites prevent *C. botulinum* growth in meats and sausages smoked at low temperatures.[37] Citrate is added to canned fruits to chelate divalent cations essential for *C. botulinum* growth.[37] Other effective means to control food contamination include the following: proper cooking and refrigeration, purification of water, pasteurization of dairy products, sanitation of food preparation surfaces with at least 1% bleach solution and 20-minute contact time, and boiling of all canned foods to remove preformed botulinum toxin.[38]

TOXINS

Physiochemical Properties

Clostridium botulinum types A, B, and F are proteolytic organisms with chromosomally encoded toxins. *C. botu-*

linum type E strains are saccharolytic bacteria with a bacteriophage-encoded toxin. *C. botulinum* type G has a plasmid-encoded toxin. Botulinum neurotoxins differ slightly in chemical makeup and mechanisms of toxicity; however, clinical manifestations of all types of botulism are similar.[39] In the United States, types A and B cause the majority of infant, foodborne, and wound botulism cases.[4] Optimum temperatures for growth of *C. botulinum* are 78 °F–95 °F (25 °C–35 °C) for proteolytic types A and B, and 38 °F–77 °F (3 °C–25 °C) for the cold-tolerant, saccharolytic type E.[34,40] Bacteria proliferate more slowly at 118 °F (48 °C), but do not die until heated to 212 °F (100 °C).[41] Spores must be heated for several hours at 212 °F (100 °C) before complete inactivation.[42] Botulinum toxin is synthesized as one of three distinct progenitor toxin complexes: 19s (900 kDa), 16s (500 kDa), or 12s (300 kDa).[43] Synthesis of assorted progenitor toxin complexes depends on antigenic type. Each progenitor toxin is composed of a nonneurotoxic component and a unique 150 kDa active neurotoxin.[44] The nonneurotoxic component of each progenitor toxin contains hemagglutinins and other proteins that protect the 150 kDa neurotoxin from acid and protease degradation in the gastrointestinal tract and blood.[45] The 150 kDa neurotoxin consists of a 100 kDa heavy chain and a 50 kDa light chain linked by a disulfide bond, which must remain intact before the neurotoxin enters nerve cells. The heavy chain binds to neuronal membrane receptors; the light chain is a zinc-dependent metalloprotease that mediates neurotoxicity.[46] See Table 15.1 for properties and characteristics of *C. botulinum*.

Mechanism of Toxicity

Foodborne botulism is caused by consuming preformed neurotoxins of *C. botulinum* in foods.[4] Infant botulism is a tandem infection-intoxication, beginning with ingestion of *C. botulinum* spores, gastrointestinal tract proliferation, and neurotoxin production *in vivo*.[11] Wound botulism is caused by neurotoxin production from wounds infected with *C. botulinum*.[47,48] Botulinum toxin binds with moderate affinity to cells in the gastrointestinal tract. The nonneurotoxic portion of the botulinum progenitor toxin binds to receptors on the apical surfaces of gastric and epithelial cells. These cells transcytose the progenitor toxin-receptor complex to the basolateral surface, where the complex enters the lymphatic circulation.[49] Following aerosolized exposure, progenitor toxin crosses the epithelial cells of the lung

TABLE 15.1. Characteristics of *Clostridium Botulinum* Antigenic Types

	A	B	C	D	E	F	G
Infant	50%	50%	–	–	–	<1%	–
Foodborne	50%	25%	–	–	25%	<1%	–
Wound	80%	20%	–	–	–	–	–

Geographic predominance	Western US[a]	Eastern US[b]	US wetlands		Pacific Northwest, Great Lakes	California, Denmark	Argentina
Common food sources	Home-processed vegetables, fruits, meats; rare commercial foods		Fish (Disease occurs in fish-eating animals.)		Alaska Native foods	Meat, seafood, jerky	Unknown
Cell inactivation	100 °C (212 °F) (>25 minutes) pH < 5.2				100 °C (212 °F) (>1 minute) pH < 4.8	100 °C (212 °F) (>25 minutes) pH < 5.2	
Spore inactivation	100 °C (212 °F), >2 hours, pH < 4.6 Spore germination slows at 60 °C (140 °F), but may resume several hours after cooling.						
Toxin inactivation	80 °C (176 °F), >15 minutes						

[a]US states with no reported foodborne botulism: Delaware, New Hampshire, South Carolina, Vermont.
[b]US states with no reported infant botulism: Maine, Rhode Island, South Carolina, Minnesota.

in a similar manner.[5] The nonneurotoxic component of progenitor toxin protects the 150 kDa neurotoxin from serum proteases during transit through the blood and lymphatic systems.[50] The neurotoxin binds preferentially to presynaptic cholinergic neurons at ganglionic synapses, postganglionic parasympathetic synapses, and neuromuscular junctions.[51,52] The 50 kDa C-terminal of the neurotoxin heavy chain binds to protein and carbohydrate moieties on the outer presynaptic membrane: synaptotagmins I and II, and polysialogangliosides GD1b and GT1b.[53,54] The 50 kDa N-terminal of the neurotoxin heavy chain subsequently translocates through the neuronal membrane, culminating in endocytosis of neurotoxin-receptor complex by the presynaptic neuron.[55] The low acidity of the endosome severs the neurotoxin disulfide bond via proteolysis to separate the 100 kDa heavy chain from the 50 kDa light chain; the light chain then penetrates the endosomal membrane to enter the cytosol.[56] The light chain prevents the docking of acetylcholine-containing synaptosomes to a multimeric transport complex on the presynaptic membrane (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor [SNARE] complex). The SNARE complex mediates the release of acetylcholine into the synapse.[57] Types A, C, and E light chains disrupt the SNARE complex by hydrolyzing unique locations on a 25 kDa synaptosomal-associated protein (SNAP-25).[58] Types B D, F, and G light chains disrupt the acetylcholine-containing synaptosome by hydrolyzing unique locations on a vesicle-associated membrane protein complex (VAMP/synaptobrevin II).[59] Type C hydrolyzes an additional SNARE protein called syntaxin.[60] Each of these mechanisms results in irreversible inhibition of acetylcholine exocytosis, resulting in clinical findings consistent with acetylcholine deficiency in the cranial nerves, parasympathetic nervous system, and neuromuscular junctions.[61] Botulinum toxin does not cross the blood–brain barrier. Consequently, central nervous system effects are generally absent and deep tendon reflexes remain intact.[62] Nausea, vomiting, abdominal discomfort, and constipation arise from paralytic ileus inflicted by the neurotoxin.[63] Brief diarrhea may occur early in the course of infant or foodborne botulism, sometimes as a result of the effects of coexisting gastrointestinal microorganisms or toxins in the offending food.[64] Saccharolytic enzymes of *C. botulinum* type E cause more prominent gastrointestinal symptoms before neurotoxicity.[65–67]

DOSE RESPONSE

Botulinum toxin is one of the most potent toxins known. The lethal dose of botulinum toxin following ingestion is approximately 1 μg/kg, whereas the lethal dose following inhalation probably is substantially less (i.e., about 100 times).[68] The typical dose of BOTOX® is 4–20 units with a therapeutic range up to 300 units. Based on primate studies, the approximate lethal parenteral dose in humans is about 40 U/kg with each unit being the estimated median lethal dose (LD_{50}) for mice.[69] A case report associated the development of botulism with the intradermal administration of high doses of unlicensed botulinum toxin A secondary to a dilution error.[70] This error resulted in the intradermal injection of up to 2,857 times the estimated human lethal dose of botulinum toxin. The patient required prolonged ventilation and physical rehabilitation.

Infants are particularly susceptible to spore-derived botulism because of the ineffective production of clostridial spore-destroying stomach and bile acids along with a relative deficiency of protective gastrointestinal bacterial flora to compete for colonization.[71] Formula-fed infants are relatively protected from spore-derived botulism compared with solely breastfed infants, presumably because of gut colonization with enterococci and coliforms earlier in life.[72,73] After infants begin eating solid food, increased stomach acid production and the increase in gastrointestinal flora tend to resist bacterial colonization.[71] Risk factors for older children and adults include inflammatory bowel disease, achlorhydria, acid-reducing medications (e.g., proton pump inhibitors, antacids), and diminished gastrointestinal flora from recent antibiotic usage.[74,75]

CLINICAL RESPONSE

Rare case reports associate limited paresis and dysphagia with the intradermal and intramuscular use of botulinum toxin A for medicinal purposes.[76,77]

Foodborne Botulism

Foodborne botulism occurs after ingestion of preformed toxin. Onset of symptoms typically occur 6–36 hours after exposure; however, a delay of up to 10 days is rare but may occur.[78,79] All adult forms of botulism manifest similar symptoms. Early symptoms of foodborne botulism include nausea, vomiting, abdominal discomfort, and constipation. These nonspecific symptoms may not initially prompt the patient to seek medical attention, and occasionally botulism presents with gastrointestinal symptoms and minimal cranial nerve dysfunction.[80] Speech disturbances including dysarthria and dysphonia are very common along with dysphagia and mild anticholinergic symptoms (dry mouth, dilated pupils, decreased bowel and bladder motility). A symmetrical progressive descending paralysis begins with bulbar paralysis including paralysis of accommodation, diplopia, lateral rectus

palsy (strabismus), oculomotor palsy (ptosis), and paralysis of respiratory muscles (intercostal, diaphragm). An acute generalized flaccid paralysis follows, but sensory deficits and central nervous system involvement is absent.[4] The clinical features of botulism progress over 1–3 days. This pattern of paralysis mimics the Miller-Fisher variant of Guillain-Barré syndrome. However, the clinical presentation of this disease often involves sensory paresthesias, absent deep tendon reflexes, and elevated cerebrospinal fluid (CSF) protein, whereas the clinical features of botulism include normal sensation, diminished or normal deep tendon reflexes, and normal CSF protein.[81,82] The combination of early bulbar findings, descending paralysis including large skeletal muscle groups, normal mental status, and normal temperature is highly suggestive of botulism. The presence of fever does not exclude the diagnosis of botulism.[83] Although the anticholinergic syndrome and botulism share many peripheral findings, the characteristic absence of changes in mental status, memory, temperature, and heart rate indicates botulism.[84] Vital signs are typically normal with the exception of low oxygen saturation secondary to respiratory insufficiency. Occasionally, paresthesias or asymmetric limb weakness occurs.[85] Differential diagnosis for botulism includes anticholinergic syndrome, Guillain-Barré syndrome, encephalitis, meningitis, hypermagnesemia, multiple sclerosis, myasthenia gravis, poliomyelitis, stroke, and tick paralysis.[86–88] Table 15.2 illustrates the clinical and diagnostic features that differentiate botulism from similar conditions.

Infant Botulism

Infant botulism affects over 100 infants per year in the United States; 95% of infant cases occur between the ages of 3 weeks and 6 months of age at presentation (median: 13 weeks).[72] Infant botulism occurs after spore ingestion, germination, and production of botulinum toxin in the gut. Symptoms develop 3–30 days after exposure. The first symptom of infant botulism is usually constipation, followed gradually by poor head control, feeding difficulties with poor sucking and swallowing, weak cry, and generalized weakness or floppiness.[89] Constipation typically precedes symptoms of weakness by several weeks. A brief period of diarrhea (19%) may precede constipation (73%).[72] Classic bulbar signs may be subtle and difficult to recognize in infants; however, diminished tracking (i.e., ophthalmoplegia) and loss of smile or facial grimace suggest bulbar involvement.[72] Seizures are rarely associated with infant botulism. Infants with botulism may be dehydrated from poor oral intake; tachycardia may accompany infant botulism secondary to dehydration in contrast to the bradycardia associated with adult botulism.[72] Dry mouth, decreased urination, and hypoactive bowel sounds also occur. The differential diagnosis includes failure-to-thrive, septicemia, congenital and acquired hypotonic disorders, Guillain-Barré syndrome, myasthenia gravis, and poliomyelitis.[72] Older children and adults with risk factors for gut colonization can develop botulism from spore ingestion.[90] Overall, botulism mortality rate since 1950 is about 2% with the case fatality rate <1% for infants hospitalized with botulism.[4] Botulism is part of the differential diagnosis of sudden infant death syndrome (SIDS),[91] but the causal role of botulism in SIDS is unclear.[92]

Wound Botulism

Wound botulism occurs after botulinum toxin is absorbed from traumatic wounds colonized with

TABLE 15.2. Distinguishing Clinical and Diagnostic Features in the Differential Diagnosis of Botulism*

Disease	Distinguishing Clinical and Diagnostic Features
Botulism	Normal temperature, normal mental status, normal heart rate, diminished or normal reflexes, normal CSF/CT/MRI, descending generalized flaccid paralysis, negative edrophonium test. EMG: Normal sensory/motor nerve conduction; brief small, abundant potentials
Antimuscarinic syndrome	Fever, altered mental status, tachycardia, intact skeletal muscle strength
Encephalitis/meningitis	Fever, altered mental status, abnormal CSF
Guillain-Barré syndrome	Sensory paresthesias, absent deep tendon reflexes, and elevated CSF protein, ascending paralysis (except Miller-Fisher variant)
Hypermagnesemia	High magnesium level
Multiple sclerosis	Abnormal CSF, MRI, nerve conduction studies
Myasthenia gravis	Positive edrophonium test, acetylcholine receptor antibodies, response to pyridostigmine
Poliomyelitis	Muscle pain and tenderness EMG: Motor axon dysfunction, sharp waves, fibrillation
Stroke	Abnormal CT/MRI, focal paralysis
Tetanus	Rigid/spastic paralysis
Tick paralysis	Ascending paralysis, identification of tick

*CSF indicates cerebrospinal fluid; CT, computed tomography; EMG, electromyogram; MRI, magnetic resonance imaging.

C. botulinum. The incubation period is 4–14 days. Clinical findings are similar to foodborne and infant botulism;[93,94] the diagnosis is often delayed in drug users presenting with early complaints consistent with bulbar palsy.[95] Fever may accompany wound botulism secondary to wound infection from other microorganisms.[93] Wound botulism is an occasional complication of illicit drug use, particularly following "skin popping" with Mexican black tar heroin.[47] The differential diagnosis includes Eaton-Lambert syndrome, hypermagnesemia, aminoglycoside toxicity, Miller-Fisher variant of Guillain-Barré syndrome, diphtheria in unimmunized patients, and myasthenia gravis.[96] Tetanus primarily affects the central nervous system and produces spasticity along with cranial nerve deficits. Tick paralysis produces an ascending rather than a descending paralysis, and poliomyelitis causes a more asymmetric ascending paralysis, primarily in the lower extremities.

Inhalational Botulism

Aerosolized exposure to botulinum toxin does not occur naturally, and airborne botulism is highly suspicious of an intentional release during terrorist acts. The clinical syndrome is probably similar to foodborne botulism without prodromal gastrointestinal symptoms. Inhalational botulism developed in three laboratory technicians beginning 3 days after performing an autopsy on a laboratory animal with botulism. Clinical features included dysphagia, ocular paresis, rotatory nystagmus, dysarthria, dilated pupils, ataxia, and generalized weakness. All 3 patients recovered after 2 weeks of treatment with botulinum antitoxin. Suspected events should be reported to the CDC or local public health departments immediately.[5]

DIAGNOSTIC TESTING

Analytical Methods

Culture of *C. botulinum* bacteria from patient specimens confirms the diagnosis of botulism; however, bacteria are rarely recovered.[97] Routine laboratory diagnosis of botulism is based on the detection of botulinum neurotoxin in the serum, feces, gastric contents, wound swabs of the patient, or in the food source, if applicable. Specimens should be obtained as early as possible after presentation, and transported in anaerobic media under refrigerated conditions (4°C/39°F). Neurotoxin detection is based on a mouse lethality assay. Mice are injected intraperitoneally with specimen extracts, alone or mixed with monovalent antitoxins (A, B, C, D, E, and F). Mice are observed for death over a 4-day period; however, death usually occurs within 24 hours with neurotoxin-positive specimens. Assays are conducted at public health laboratories and the CDC.[21] An enzyme-linked immunosorbent (ELISA) assay is an alternative to the mouse bioassay, but this immunoassay is available primarily in research laboratories.[98] More rapid molecular and biochemical methods for detecting botulinum toxin currently are being developed, such as multiplex polymerase chain reaction (PCR) assay.[99,100] AOAC International (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) official method 977.26 is applicable to the determination of *C. botulinum* and associated toxins in foods.[101]

Biomarkers

There are no human biomarkers for monitoring or surveillance of *C. botulinum*.

Abnormalities

Electrolytes, complete blood counts, CSF fluid analysis, and edrophonium tests are normal in patients with botulism. Documentation of negative studies helps to narrow the differential diagnosis to botulism, and health officials may utilize this information in an individual case to determine the potential benefit of botulinum antitoxin. The electromyogram (EMG) typically shows brief, small, abundant action potentials (BSAPs) that increase in amplitude under repetitive stimulation at 50 Hz; nerve conduction remains intact.[102] Severe dehydration results in hypernatremia (serum Na > 150 mEq/L) or hyponatremia (serum Na < 130 mEq/L), hypokalemia (serum K < 3.0 mEq/L), hypochloremia, elevated urine specific gravity (SpG > 1.020), and/or hyperphosphatemia. Low serum bicarbonate results from lactic acid production or elevated serum bicarbonate secondary to contraction alkalosis.

TREATMENT

Gastrointestinal symptoms are mild and self-limited. Affected patients may experience significant anorexia, necessitating intravenous fluid replacement and hospitalization in cases of significant dehydration or severe electrolyte abnormalities, particularly in young children or elderly patients.[103,104] Supportive care of botulism includes stabilization of airway, breathing, and circulation. Cases with bulbar findings usually progress to respiratory failure, and require mechanical ventilation.[4] Nutrition is supported with tube feedings and rarely by total parenteral nutrition.[72] Activated charcoal may be beneficial when patients present early, but there are no clinical data to confirm the efficacy of activated charcoal

for the treatment of botulism.[105] Guanidine enhances acetylcholine release from botulinum-poisoned nerve terminals *in vitro*; however, guanidine has no clear benefit *in vivo*, and is not recommended. *C. botulinum* is susceptible to a number of antibiotics (e.g., aminoglycosides, clindamycin);[106] however, antibiotics are not recommended because additional toxin is released from bacterial lysis following the administration of antibiotics.[78] The CDC offers 24-hour telephone consultation to discuss suspected cases of botulism and the appropriateness of botulinum antitoxin (day phone: 404-639-2206, night phone: 404-639-2888). The clinician may also report suspected cases to regional or state health officers, infection control officers, or poison control centers.

Treatment with antitoxin is determined through direct clinical discussion with local, state, or CDC health officials. Laboratory testing may take several hours or days to complete; treatment should be given as early as possible during the clinical course, and should occur before laboratory confirmation in cases with high suspicion.[107] Botulinum antitoxin halts the progression of illness by binding circulating, unbound toxin; toxin bound to nerve tissue is not affected by antitoxin.[108] Two primary botulinum antitoxins are available. Trivalent (A, B, E) botulinum antitoxin contains intact IgG antibodies derived from horses. This antitoxin is available from state and local health departments via the CDC. A single vial is administered after skin testing for sensitivity.[107] Horse-derived antitoxin is not recommended for infant botulism secondary to risk of allergic reactions.[109] Infant botulism may be treated with human botulism immune globulin (BabyBIG®), available through the California Department of Health Care Services (Sacramento, CA).[110] BabyBIG® is dosed at 1 mL/kg (50 mg/kg) as a single intravenous infusion. The package insert should be reviewed by the clinician for updates in dosage and administration. When used within 3 days of onset of symptoms, BabyBIG® reduces mean hospital stay from 5.7 weeks to 2.6 weeks, with significant reductions in the length of stay in the intensive care unit along with decreased duration of mechanical ventilation and of tube feedings.[111–113] Botulinum antitoxins are housed in CDC satellite pharmacies at major airports to facilitate the transportation of affected patients. Patients require continued supportive care after antitoxin administration until respiratory drive is sufficient to maintain ventilation and oxygenation without mechanical support. Many patients require extensive physical and occupational therapy during recovery. Cholinergic neurons regenerate terminal axons and new synapses over several weeks to months in successfully treated cases.[114] The US Army developed a broad heptavalent (A, B, C, D, E, F, G) botulinum antitoxin, derived from equine IgG antibodies digested with pepsin to cleave most of the Fc portion of the antibody, leaving the $F(ab')_2$ portion. This preparation is less immunogenic, and is effective against all known strains of botulism when not contraindicated. The US Department of Health and Human Services commissioned the Cangene Corporation (Winnipeg, Manitoba, Canada) to develop 200,000 doses of heptavalent botulinum antitoxin for delivery into the Strategic National Stockpile from 2007–2012.[115]

Chapter 16

CLOSTRIDIUM PERFRINGENS

Cyrus Rangan, MD, FAAP

HISTORY

Clostridium perfringens (Veillon & Zuber) Hauduroy et al. (*C. perfringens*) is a strict anaerobic, gram-positive, spore-forming bacterium that causes a variety of human and veterinary diseases. In 1892, William H. Welch and George Nuttall discovered these bacteria in gangrenous wounds. At that time, they designated the bacteria as *Bacillus aerogenes capsulatus*. Foodborne disease from *C. perfringens* was first described by L.S. McClung in 1945.[1] Although *C. perfringens* is largely recognized as the chief cause of clostridial myonecrosis (gas gangrene), it is the third most commonly reported cause of human foodborne gastrointestinal disease in the United States after *Salmonella* spp. and *Staphylococcus aureus* with 10–20 reported annual outbreaks in the United States.[2] *C. perfringens* is serotyped A–E, based on distinct combinations of major and minor clostridial toxins (e.g., alpha, beta, epsilon, iota). Epsilon toxin is a bioterrorism select agent. Serotypes A and C are associated with human disease, whereas serotypes B, D, and E are associated with veterinary diseases. All five serotypes elaborate α-toxin (a variant of phospholipase C), which is the toxin responsible for clostridial myonecrosis. About 5% of serotype A isolates also elaborate *Clostridial perfringens* enterotoxin, which mediates the vast majority of foodborne diseases from *C. perfringens*.[3] Serotype C produces β-toxin that causes rare cases of human necrotic enteritis. In Germany and Denmark during WWII, outbreaks of this necrotic form of enteritis occurred in soldiers, who were given large meals after days to weeks of starvation. The disease was named "Darmbrand."[4] In the early 1960s in Papua New Guinea, outbreaks of enteritis necroticans occurred in natives after large pig feasts lasting several days. In the native dialect, this disease was called "Pigbel." In both settings, *C. perfringens* type C was isolated in peritoneal fluid and food.[5] Most reported foodborne outbreaks associated with *C. perfringens* are mild diseases caused by *C. perfringens* type A. The term "cafeteria diarrhea" has been applied to food poisoning outbreaks from *C. perfringens* because these outbreaks often occur following consumption of meals prepared in schools, prisons, hospitals, and cruise ships.

EXPOSURE

Source

Environment

Clostridial perfringens spores are ubiquitous in soil and sediment, especially in areas that receive runoff from animal or human feces.[6,7] This bacteria is part of the normal intestinal flora of both humans and animals. However, only a few strains carry the specific *C. perfringens* enterotoxin gene encoded for the production of the enterotoxin, which causes food poisoning.

Animal

Clostridial perfringens colonizes and sporulates in the intestines of asymptomatic humans and various animals including poultry, cattle, and domestic pets.[8] These bacteria may also contaminate poultry feeds. A necrotic

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

enteritis and a subclinical form of *C. perfringens* infections occur in poultry as a result of colonization by α-toxin producing type A strains and, to a lesser extent, by α- and β-toxin producing type C strains. Predisposing factors to the development of these diseases in poultry include coccidial-induced mucosal damage and diets high in indigestible, water soluble, nonstarch polysaccharides. Lactose supplementation and reduction of rye in the diets of poultry result in significant reductions in colonization by *C. perfringens*.[9]

Food

Undercooked or inadequately stored meats, poultry, meat stocks, stews, and gravies constitute the vast majority of food sources responsible for outbreaks of *C. perfringens*-induced food poisoning.[10] However, any food including nonanimal protein (e.g., spinach boiled with fried bean curd) that undergoes slow cooling or inadequate reheating (<65 °C/149 °F) is a potential source of human exposure to *Clostridium perfringens*.[11,12] In a US survey of about 900 raw, retail foods unassociated with any food poisoning outbreaks, approximately 1.4% of the foods contained *C. perfringens* isolates carrying the enterotoxin gene.[13] The development of *C. perfringens*-induced cases of food poisoning typically require high bacterial counts with isolates that contain the enterotoxin gene (*cpe*).[14]

Food Processing

Sufficient refrigeration and adequate reheating of meat-containing dishes stored after cooking are the best methods for preventing germination of spores.[15,16] The addition of table salt (NaCl) to uncooked meats (e.g., ham, beef) restricts growth and sporulation of *C. perfringens*.[17] Growth is also inhibited by the addition of organic acids (e.g., sodium citrate, sodium lactate) to vacuum-packaged foods.[18] Proper disinfection and the use of separate utensils and containers for cooked and uncooked food may help prevent cross-contamination of cooked food.[19,20]

TOXINS

Physiochemical Properties

Type A Clostridia Enterotoxin

Clostridial perfringens is a gram-positive, spore-forming anaerobic bacterial rod that germinates at a wide variety of temperatures (12 °C–50 °C/54 °F–122 °F) and pH (5.0–9.0). Spores survive domestic cooking (>60 °C/140 °F) and freezing (<4 °C/39 °F) temperatures. *C. perfringens* enterotoxin (CPE) is a 35 kDa heat-labile protein stored by *C. perfringens* type A in paracrystalline inclusion bodies during sporulation.[21] Upon lysis of the mother cell in 8–24 hours, both CPE and the spore are released.[22] The link between spore formation and CPE production is well established, and enterotoxin-negative spore-forming strains of *C. perfringens* do not cause food poisoning.[24] The gene (*cpe*), which encodes CPE, lies on a chromosome rather than a plasmid; therefore, *C. perfringens*-associated food poisoning usually requires a relatively large inoculation to produce enough CPE to cause disease. Although most cases of *C. perfringens*-induced food poisoning involve heat-resistant (i.e., 100 °C/212 °F for >10 minutes), *cpe*-chromosomal-borne strains, occasionally heat-sensitive, *cpe*-plasmid-borne strains cause outbreaks of food poisoning.[23]

In cases of sporadic (nonfood-related poisoning) diarrhea from *C. perfringens*, CPE is encoded on a plasmid that transfers to normal gastrointestinal flora for subsequent transcription.[24] Consequently, only a few organisms are required to cause disease.[25] Only a small percentage of *C. perfringens* isolates are positive for the *cpe* gene. *C. perfringens* type C elaborates a plasmid-encoded β-toxin that is easily degraded by trypsin produced by the pancreas. In contrast to the plasmid-encoded β-toxin, the presence of trypsin enhances CPE activity.[26] All *C. perfringens* serotypes elaborate α-toxin that is structurally similar to the enterotoxic phospholipases produced by *Bacillus cereus*.[27]

Epsilon Enterotoxin and Serotype B–E Clostridial Perfringens Toxins

Table 16.1 displays the serotypes of *C. perfringens* isolates and the associated diseases and toxins. Epsilon enterotoxin is a 33-kDa protein produced by serotypes B and D. These strains produce fatal hemorrhagic enteritis in lambs and goats.[28] This clostridial toxin is the third most lethal of all clostridial toxin, ranking behind only tetanus and botulinum neurotoxins. Epsilon toxin is considered a potential bioterrorism agent because of the ability of this toxin to produce diffuse edema, renal damage and neurotoxicity.[29] This toxin is synthesized as an inactive proto-toxin that requires proteolytic activation by intestinal proteases (trypsin, α-chymotrypsin) prior to systemic absorption.

Mechanism of Toxicity

Both spores and vegetative cells of *C. perfringens* are found in many foods. Cooking destroys vegetative cells, but spores survive to germinate when food is cooled to room temperature. *C. perfringens* type A produces *C. perfringens* enterotoxin that ultimately erodes the intestinal mucosa by disrupting epithelial tight junctions. The

TABLE 16.1. Diseases and Toxins Associated with Types of *Clostridial Perfringens*

Type	Major Toxins[a]	Diseases
A	α	Human myonecrosis (gas gangrene), necrotic enteritis in fowls, enterotoxemias of cattle and lambs, mild necrotizing enteritis of piglets
	α, CPE	Human food poisoning, human nonfoodborne gastrointestinal disease, veterinary diarrhea
	α, CPE, β_2	Human nonfoodborne gastrointestinal disease
	α, β_2	Porcine enteritis
B	α, β, ε	Dysentery in newborn lambs, chronic enteritis in older lambs, hemorrhagic enteritis in neonatal calves and foals, hemorrhagic enterotoxemias in sheep, biodefense concerns
C	α, β	Human necrotizing enteritis (Pigbel, Darmbrand), enteritis in hemorrhagic/necrotic enterotoxemias in neonatal pigs, lambs, calves goats, and foals, acute enterotoxemia (struck) in adult sheep
	α, β, β_2	Porcine enteritis
D	α, ε	Enterotoxemia in lambs (pulpy kidney disease) and calves, enterocolitis in neonatal and adult goats and cattle, biodefense concerns
E	α, ί	Canine, bovine, porcine enteritis

Source: From Ref 29.
[a]Major *C. perfringens* toxins include alpha (α), beta (β), epsilon (ε), and iota (ί), and enterotoxin (CPE).

lysis of the vegetative cells during sporulation releases *C. perfringens* enterotoxin into the intestines. The enteric toxins of *C. perfringens* are all single polypeptides of modest size (25–35 kDa) that form pores or channels in plasma membranes of host cells.[30] Structure and function of tight junctions are maintained by membrane-spanning proteins called claudins and occludins. *C. perfringens* enterotoxin (CPE) first induces shortening of the intestinal villi and desquamation of the epithelial lining, primarily in the ileum. Then CPE binds preferentially to claudins 3, 4, 6, 7, 8, and 14 (but not to claudins 1, 2, 5, or 10) on the apical membrane of epithelial cells. This specific interaction produces a large disruptive protein complex that stimulates the influx of calcium into the cell.[31] Calcium binds and activates calmodulin and calpain, releasing intracellular stores of calcium and the subsequent depolarization of mitochondrial membranes.[32] Mitochondrial cytochrome C is released into the cytosol, where an apoptosome (i.e., a moiety that mediates apoptosis) forms with the large CPE protein complex. The apoptosome activates intracellular caspase-3, which enters the cell nucleus and cleaves DNA, resulting in cell damage.[33] This damage exposes the basolateral membrane of the epithelial cell that houses the occludins. *C. perfringens* enterotoxin binds to these occludins, thus finalizing the compromised integrity of epithelial tight junctions. Major alterations in cell permeability ensue, as water, proteins, and fragmented epithelial cells pour into the intestinal lumen.[34] Mucosal tissue degradation by CPE is aided by α-toxin-mediated binding to phosphatidylcholine and sphingomyelinase on intestinal cell membranes. CPE is structurally similar to the phospholipases produced by *Bacillus cereus.*[27] *C. perfringens* type C β-toxins are internalized by epithelial cells, where they oligomerize to form pores in the basolateral membrane and induce cell death.[35] There are limited data suggesting that β-toxins produce neurotoxic effects, resulting in damage to preganglionic sympathetic fibers and subsequent vasoconstriction.[36] A chronic low-protein diet (e.g., sweet potatoes rich in heat-stable trypsin inhibitors) predisposes individuals to the toxic effects of β-toxin.[37]

DOSE RESPONSE

The onset of gastrointestinal symptoms requires significant bacterial replication in the gastrointestinal tract, characterized by stool colony counts of $\geq 10^6$ CFU/g. In a human volunteer study, an inoculum of a minimum 5×10^8 viable vegetative *C. perfringens* bacteria were necessary to produce diarrheal symptoms in 100% of subjects.[14]

CLINICAL RESPONSE

Clostridial perfringens food poisoning is characterized by abdominal cramping and diarrhea with or without blood after an incubation period of 8–24 hours. Fewer than 20% of patients experience fever or vomiting. Symptoms usually persist for 24 hours.[38] The presentation is clinically similar to the diarrheal syndrome caused by enterotoxigenic strains of *B. cereus*.[39] Case reports indicate that potential fatal acute necrotizing enterocolitis can occur following foodborne CPE-positive *C. perfringens* type A infection.[40,41] Food poisoning from *C. perfringens* serotype C (pigbel) is characterized by bloody diarrhea, fever, and rare cases of bowel ischemia, perforation, and peritonitis.[42,43]

DIAGNOSTIC TESTING

Analytical Methods

The symptoms associated with *C. perfringens* are usually self-limiting, and routine analytical testing for *C. perfringens* is unnecessary. Verification of these bacteria as the source of food poisoning requires identification beyond the species level because of the ubiquitous presence of these bacteria in humans, animals, soil, and surface water. Bacterial strain typing methods aid the epidemiological investigations of the sources, limit the spread of the food poisoning outbreak, and supply information on the contamination of food for the improvement of food distribution. For epidemiological purposes, traditional phenotypical methods (biotyping, serotyping and phage typing of isolates, antimicrobial susceptibility testing) provide insufficient information to track the source of a food poisoning epidemic in contrast to molecular methods. During epidemiological studies, isolation of *C. perfringens* strains from stool, vomit, or leftover food is performed by molecular methods including hydrophobic grid membrane filter-colony hybridization (HGMF-CH), pulse-field gel electrophoresis (PFGE), ribotyping,[44] and plasmid gene profiling.[45,46] The toxins of *C. perfringens* can also be identified by latex agglutination and by enzyme-linked immunosorbent assay (ELISA).[47] Bacteria can be analyzed for the presence of the *cpe* gene by polymerase chain reaction (PCR) and Western blot if the toxin is not identified directly.[23,48] In contrast to serological methods, PCR-based assays do not require the isolates to sporulate *in vitro* before detection. However, PCR identifies *C. perfringens* isolates as *potentially* enterotoxigenic because some isolates carry a silent, unexpressed *cpe* gene.

Biomarkers

Confirmation of *C. perfringens*-induced food poisoning includes direct assay for CPE by reversed passive latex agglutination test,[49] detection of $\geq 10^5$ *cpe*-positive colony count/g in food, $\geq 10^6$ *cpe*-positive colony count/g in stool, and type-to-type serotype confirmation of stool to food.[14] The presence of all four criteria provides definite proof of *C. perfringens* food poisoning. However, sufficient testing material may not be present to meet all four criteria, and a presumptive diagnosis of *C. perfringens* food poisoning can be made with fewer criteria.

Abnormalities

Clostridial perfringens food poisoning can produce severe serum electrolyte abnormalities including hypernatremia (serum Na > 150 mEq/L), hyponatremia (serum Na < 130 mEq/L), hypokalemia (serum K < 3.0 mEq/L), and hypochloremia, as well as elevated urine specific gravity (SpG > 1.020). Low serum bicarbonate results from diarrhea-induced, chloride-responsive, non-anion gap metabolic acidosis. Other laboratory abnormalities include lactic acid production or elevated bicarbonate secondary to contraction alkalosis. The short duration of disease induced by *C. perfringens* limits the severity of fluid and electrolyte imbalances that usually resolve spontaneously.[50]

TREATMENT

Treatment is primarily supportive including rehydration and bowel rest for the diarrheal syndrome. Oral rehydration is usually sufficient, but intravenous fluid replacement and hospitalization may be necessary in cases of severe dehydration or severe electrolyte abnormalities, particularly in young children or elderly patients.[51,52] There are no clinical trials that demonstrate an improvement in clinical outcome, avoidance of hospitalization, or shortened duration of symptoms following the use of either antiemetics or antidiarrheal agents. The short duration of symptoms usually limits the need for these medications; however, some patients may experience symptomatic relief with these agents when symptoms are severe. Although antimicrobials are beneficial in cases of clostridial myonecrosis, these drugs are not routinely used in most cases of *C. perfringens* foodborne poisoning, even when symptoms are prolonged.[35] Enteritis necroticans should be evaluated with prompt surgical consultation and aggressive supportive care to maintain fluid and electrolyte balance.[42]

Chapter 17

ESCHERICHIA COLI

Cyrus Rangan, MD, FAAP

HISTORY

Escherichia coli (Migula) Castellani and Chalmers (*E. coli*) are lactose-fermenting, gram-negative, facultative anaerobic rods, first isolated and characterized by Austrian pediatrician and bacteriologist Theodor Escherich in 1885.[1] Since that time, over 170 serogroups of *E. coli* have been identified that are distinguished by the expression of O (somatic), H (flagellar), and/or K (capsular) antigens. Over the last part of the 20th century, several groups of pathogenic *E. coli* have been identified. Of these serotypes, 43 enterohemorrhagic serotypes of *E. coli* (EHEC) are associated with bloody diarrhea.[2] *E. coli* O157:H7 has emerged as the most notorious enterohemorrhagic *E. coli* serotype based on the threat of these infections to public health. The first recognized outbreak of *E. coli* O157:H7 occurred in 1982, when an outbreak of food poisoning ("hamburger diarrhea") resulted from the contamination of hamburger with this *E. coli* serotype.[3] In the United States, *E. coli* O157:H7 remains among the most common organism isolated from patients with bloody stool specimens.[4] Enteropathogenic *E. coli* were the first disease-causing strains of *E. coli* identified, and these strains of *E. coli* remain a common cause of diarrhea in children ("infant diarrhea"), particularly in developing nations. During the 1960s, enterotoxigenic strains of *E. coli* were recognized as a cause of "traveler's diarrhea." Enterotoxigenic strains of *E. coli* remain a major cause of travel-associated diarrhea (Asia, Mexico, Latin America, Africa), as well as gastrointestinal illness in military settings. Recently, enteroaggregative strains of *E. coli* have been associated with persistent watery diarrhea in developing countries. Each year, 73,000 cases of pathogenic *E. coli* illness are reported worldwide, resulting in over 60 deaths.[5]

EXPOSURE

Classification

Enterovirulent strains of *E. coli* are important causes of foodborne illness, and there are four major groups: enterohemorrhagic (EHEC), enteropathogenic (EPEC), enteroinvasive (EIEC), and enterotoxigenic (ETEC). In addition, there are two new enterovirulent groups that include enteroaggregative (EAggEC), and diffusely adhering (DAEC) *E. coli*. In contrast to other pathogenic *E. coli* groups, the toxicity of EIEC is not limited to the intestinal mucosal surface.

Source

Environment

Worldwide, the most common environmental sources of *E. coli* infections are drinking water, feces, and sewage. In particular, public swimming pools and lakes are frequent sources of community exposure to *E. coli*.[6] Environmental contamination may persist for up to 10 months, resulting in latent infections.[7] Chlorination adequately minimizes the risk of *E. coli* in drinking water.[8]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Animal

Escherichia coli survive in the intestines of various animal reservoirs including rabbits,[9] sheep,[10] healthy cattle, deer,[11] and humans.[12] These reservoirs potentially include both ruminants (cattle, sheep, goats, buffalo, deer, elk, giraffes, camels) and monogastric animals (humans, pigs, chickens, rabbits). Food and water sources may be contaminated directly by human or animal feces. Well-fed cattle with high volatile fatty acid diets, low intestinal pH, and low lactate concentrations usually have lower *E. coli* colony counts than fasted, poorly fed cattle.[13] In animal models, the consumption of corn contaminated by the mycotoxin, fumonisin B_1, is associated with increased intestinal colonization of *E. coli*.[14] Concomitant ingestion of *E. coli* and ochratoxin increases mortality in chickens.[15] Cattle are resistant to the effects of *E. coli*-derived toxins as a result of the difference in expression of toxin receptors between humans and animal reservoirs.[16,17]

Food

Humans contract *E. coli* from raw food, processed food, and beverages. Person-to-person transmission during outbreaks of *E. coli* infections is common, particularly in day care centers and nursing homes.[18] Foods left outdoors for extended periods of time are particularly vulnerable to *E. coli* contamination. Attendance at agricultural fairs is an epidemiological risk factor, and may contribute significantly to summer peak incidence of *E. coli* exposures in the United States.[19] In addition to food, *E. coli* contaminates herbal dietary supplements, when bacterial contamination results from inappropriate manufacturing methods.[20] The distribution of dietary supplements in the United States is regulated by the Dietary Supplement Health and Education Act of 1994. Good manufacturing practices have been established for the formulation of these herbal dietary supplements including a zero tolerance for the presence of pathogens.[21] Infections from *E. coli* O157:H7 strains occur sporadically in the United States, and occasionally outbreaks result from the ingestion of contaminated food (e.g., raw spinach).[22]

Although ground beef is a common source of EHEC, other food sources include potatoes, alfalfa sprouts, unpasteurized fruit juice, dry-cured salami, deer jerky, lettuce, game meat, cheese curds, artichokes, raw unpasteurized cow's milk, hard taco shells, coleslaw, fruit salads, and drinking water.[23–26] Typical foods associated with contamination by EPEC and EIEC are not well defined. Potential sources of contamination by these *E. coli* serotypes include raw meats, unpasteurized milk, imported cheese, guacamole, and contaminated water, or any other food source exposed to human or animal feces. Infantile disease associated with these serotypes suggests the use of *E. coli*-contaminated water for the mixing of bottled baby formula.[27] Human feces is the primary source of ETEC; potential sources include dairy products, semisoft cheeses, raw fruits and vegetables, tabbouleh, parsley, raw seafood, meat, poultry, and untreated water. Outbreaks of ETEC in the United States have occurred at a Mexican restaurant, a hospital cafeteria, and on a cruise ship due to ETEC-contaminated food and water.[27,28]

Food Processing

All phases of food handling and processing permit the potential entry of *E. coli* into the food supply. *E. coli* does not survive in temperatures above 155 °F (68 °C) during cooking, and *E. coli* is sensitive to virtually all commercially available alkaline cleaners in the food industry. However, exposure to a cleaner confers some cross-protection to heat.[29] Contamination of produce occurs following contact with cattle manure-based fertilizers, improperly sanitized equipment, or inadequately cleaned produce. Cattle feed derived from chicken manure must be properly stored for 4–8 weeks, during which time naturally produced temperatures of 160 °F–170 °F (71 °C–77 °C) destroy bacteria including *E. coli*. Irrigation water increases the risk of contamination when recycled water is used on fertilized fields. Because *E. coli* can thrive on both food and on unclean food handling equipment, public health regulations require food handlers to maintain short fingernails and to scrub the nails with soap and nailbrush.[30] Proper hygiene during harvesting, slaughtering, transportation, storage, and packaging are extremely important to reduce the risk of contamination. High risk of *E. coli* contamination occurs during certain food processes, such as the reworking of ground beef when leftover beef is stored until the next day's production run. This process also reduces the ability to trace sources of *E. coli* when outbreaks of food poisoning occur. Although irradiation is an approved method for infection control in chicken and produce, this process is not widely used as a result of issues related to consumer concern and acceptance. *E. coli* cross-contamination occurs also during food transportation and storage, especially if vehicles or facilities are used alternately for both fertilizer and food. Refrigeration can slow the rate of growth of *E. coli*, but this process does not kill bacteria or bacterial toxins, and EHEC survives freezing in ground beef. Therefore, refrigeration does not alter previous *E. coli* contamination.

Escherichia coli O157:H7 contains a genetic sequence that controls intrinsic resistance to multiple structurally and functionally unrelated antibiotics added during

food processing.[31] The hemolytic, antimicrobial peptide dermaseptin is optimally bactericidal to *E. coli* at high NaCl concentrations, low pH, and temperature extremes. Consequently, dermaseptin is a useful food preservative for multiple phases of food processing.[32] Nontoxic, probiotic *E. coli* strains produce colicin, a natural antibacterial compound that has the potential to compete for pathogenic *E. coli* in cattle reservoirs.[33] Experimental *in vitro* evidence suggests the efficacy of the combination of nisin and cinnamon to inactivate *E. coli* in homemade apple juice.[34]

TOXINS

Physiochemical Properties

Enterohemorrhagic Escherichia Coli

Bacteria-derived effector molecules and a special mechanism called the type-III secretion system (TTSS) determine the virulence of EHEC. Diffusely adhering *E. coli* also possess a TTSS mechanism, making it a potentially virulent form of *E. coli*.[35] EHEC and EPEC genomes contain a 35-kbp pathogenicity island called the locus of enterocyte effacement (LEE), which codes for three protein sets: adhesive intimin on the outer bacterial membrane;[36] *E. coli* secretory proteins (*EspA*, *EspB*, and *EspD*);[37] and translocated intimin receptor (*Tir*). These three proteins interact to anchor bacteria to intestinal epithelial cells.[38] EHEC contain additional loci encoding enterotoxins called Shiga toxins (*Stx1* and *Stx2*), which are nearly identical to the enterotoxins of *Shigella flexneri*.[39,40] The structure (A subunit linked to five B subunits) and functions of these Shiga toxins and cholera toxin are similar. EHEC also produce a colonic acid slime polysaccharide to combat extremes in physiologic stress such as pH and temperature,[41] adding the inherent ability of *E. coli* to survive gastric acid.[42]

Enteropathogenic Escherichia Coli

EPEC possess an identical TTSS, secreting the same series of proteins that enable it to anchor to intestinal epithelial cells. However, EPEC do not elaborate toxins.

Enteroinvasive Escherichia Coli

EIEC contain an invasiveness plasmid that is identical to a plasmid found in *Shigella* species. This genetic material encodes for proteins that permit epithelial invasion, bacterial proliferation, and ultimate destruction of epithelial cells. EIEC probably developed from a hybrid strain of *E. coli* and *Shigella* species, though it does not elaborate Shiga enterotoxins.[43]

Enterotoxigenic Escherichia Coli

ETEC exhibit specialized pili and fimbriae termed colonization-factor antigens (CFAs), comprised of alpha helical arrangements of lectin adhesins that enable the bacteria to colonize epithelial cell surfaces in the small intestine. The ETEC genome codes for two distinct polypeptides, a heat-stable enterotoxin (ST), and a heat-labile enterotoxin (LT), which are secreted via a type-II secretion system. ETEC strains may synthesize one or both of these toxins. LT bears a 77% genotypic resemblance to *Vibrio cholera* toxin and functions similarly.[44]

Mechanism of Toxicity

Enterohemorrhagic Escherichia Coli

EHEC induce attachment and effacement (A/E) lesions in the intestine, followed by the elaboration of Shiga toxins that cause hemorrhagic diarrhea. EHEC initially cause A/E lesions in the terminal ileum and colon. These lesions are characterized by rapid colonization and binding to the intestinal epithelium, followed by a rearrangement of the actin scaffolding of intestinal villi cells.[45,46] EHEC may initially communicate with host cells via an auto-inducer protein that cross-communicates with epinephrine secreted from intestinal cells.[47] Phentolamine, propanolol, and haloperidol interfere with the action of intestinal norepinephrine and dopamine, and diminish adherence of EHEC to cecal epithelial cells *in vitro*.[48] EHEC make first contact with epithelial cells via fimbriae on the outer bacterial membrane; these fimbriae also mediate bacteria aggregation and formation of microcolonies.[49,50] Advanced postnatal age increases adherence, due to progressive postnatal development of gut receptors for these fimbriae.[51] The type-III secretory system releases secretory proteins, beginning with *EspA*, which forms a filamentous, needle-like chute. *EspB* is exported down the chute to the surface of the intestinal epithelial cell, where it punches pores into the cell membrane. Translocated intimin receptor (*Tir*) travels down the chute and settles into the pores. *Tir* then anchors adhesive intimin that coats the outer membranes of EHEC to complete the process of the attachment.[52] Adherence stimulates host cell mediators to promote the release of stored intracellular calcium, which stimulates the enzyme villin to depolymerize the scaffold of cytoplasmic actin filaments supporting the cytoskeleton of the intestinal villi cells. Free actin microfilaments are then recruited, and they accumulate directly beneath bacteria (F-actin aggregation). In this location, they are cross-linked by the enzymes α-actinin, talin, erzin, and villin to form pedestals, completing the process of effacement and destruc-

tion of microvilli.[53] EHEC also injects cyclomodulin into host cells, halting progression to mitosis and slowing down epithelial cell turnover, which is an important human defense mechanism against gastrointestinal infections. High HCO_3 concentration increases production of intimin, *EspA*, *EspB*, and *Tir*, explaining the predilection of EHEC for the distal portions of the intestinal tract.[54]

The B subunit of the toxin binds with high affinity to Gb3 receptors on epithelial and endothelial cells. Once attachment and effacement occur, Shiga toxins bind to the membrane glycolipid globotriaosylceramide, cross the intestinal epithelial barrier, and injure host cells via inhibition of protein synthesis, stimulation of prothrombotic messages, and induction of apoptosis. After endocytosis, the intact toxin travels to the endoplasmic reticulum via the Golgi apparatus, where cleavage of the A1 and A2 subunits occurs.[55] Release of the A1 subunit into the cytosol causes the deactivation of ribosomal RNA on the 60S ribosomal subunit. Cellular protein machinery thereby shuts down, leading to cell death, edema, hemorrhage, and subsequent bloody diarrhea.[56] EHEC also suppresses mucosal inflammation and proliferation of intraepithelial lymphocytes.[57] Shiga toxins stimulate production of proinflammatory mediators IL-1-B, IL-6, TNF-alpha, gamma-interferon, and von Willebrand factor (vWF); and suppress antiinflammatory cytokines IL-2 and IL-10. Hemolytic-uremic syndrome (HUS) is an acquired Coombs-negative hemolytic anemia with thrombocytopenia and renal failure. Following at least 6 months of recovery from hemolytic-uremic syndrome, these patients demonstrate a similar cytokine profile, suggesting a possible immunogenetic predisposition to this syndrome.[58]

Hemolytic-uremic syndrome occurs as a result of the translocation of Shiga toxins into circulatory system and the transport of these toxins by leukocytes to capillary endothelium of the renal vasculature, where they bind to renal globotriaosylceramide and are endocytosed.[39] In patients with hemolytic-uremic syndrome, plasminogen activator (vWF) and platelet aggregating factor are released from the renal endothelium, forming platelet-fibrin-hyaline thrombi at the injured sites. Platelets are consumed, and circulating erythrocytes are deformed and fragmented as they move through the occluded microvasculature. The spleen then removes the damaged erythrocytes from the circulation. Children have Gb3 receptors in multiple extraintestinal loci, namely the glomerulus. Shiga toxin binds to both glomeruli and renal tubules in toddlers, but only to renal tubules in the elderly, suggesting that the binding of *Stx* to glomeruli in children may be responsible for the appearance of hemolytic-uremic syndrome.[59] Although EHEC is clearly associated with hemolytic-uremic syndrome, the evidence linking Shiga toxin to the pathology associated with HUS remains largely indirect.

Thrombotic thrombocytopenic purpura (TTP) is a potential sequela of EHEC infection in adults. This illness shares some of the clinical features (e.g., fever, altered mental status) of hemolytic-uremic syndrome. The causes of these two illnesses are uncertain, but both begin with a similar pattern of vascular endothelial injury, resulting in microvascular lesions, platelet-fibrin-hyaline microthrombi, occluded arterioles and capillaries, and a consumptive thrombocytopenia. Microthrombi occlude the vasculature of multiple organs, including the skin, intestines, skeletal muscle, pancreas, spleen, adrenal glands, heart, and most prominently in the central nervous system, kidney, and liver.

Enteropathogenic Escherichia Coli

EPEC induce similar attachment and effacement pathology seen in EHEC in the terminal ileum and colon, but EPEC do not elaborate toxins. Instead, they induce changes in Na^+/H^+ isoform activity, leading to the accumulation of intraluminal sodium and water, and subsequent watery diarrhea.[60]

Enteroinvasive Escherichia Coli

EIEC physically invade intestinal epithelial cells of the colon, causing bloody, *Shigella*-like dysentery. A large 140–MDa plasmid confers *Shigella*-like dysentery, similar to the plasmid associated with *Shigella* gastroenteritis. Micro ulcers are produced in the wake of cell death, liberating erythrocytes, leucocytes, mucus, cell debris, and bacterial progeny. After cell death, EIEC invades superficial tissue, but neutrophils and macrophages quickly phagocytose organisms, preventing systemic dissemination. Extrusion and regeneration of colonic epithelial calls limit the disease process to 5–7 days.[43]

Enterotoxigenic Escherichia Coli

ETEC causes a secretory diarrhea mediated by bacterial endotoxins. ST and/or LT enterotoxins are elaborated after bacterial colonization on intestinal epithelial cells. LT activates adenyl cyclase, leading to increased cAMP, activation of cAMP-dependent protein kinases, and phosphorylation of the cystic fibrosis transmembrane conductance regulator. ST directly stimulates guanylate cyclase on brush border membranes of the jejunum and ileum, increasing cellular cGMP. Chloride ion flow is subsequently reversed, leading to an accumulation of chloride, sodium, and water in the intestinal lumen.[44,45]

Enteroaggregative Escherichia Coli

EAggEC exhibits a “stacked brick” adherence pattern on intestinal epithelial cells in the colon without invasion. EAggEC stool cultures are positive for fecal lactoferrin, which supports the notion that EAggEC infection is associated with an intestinal inflammatory response.[61] EAggEC produces heat-stable and heat-labile toxins that induce watery, intestinal secretions.[62]

DOSE RESPONSE

There are limited data on the inoculation size of various *E. coli* groups necessary to cause toxicity based primarily on basic research done with *Shigella* species. EHEC and EIEC require as little as 10 organisms to cause severe clinical effects, based on their functional similarities to *Shigella* spp. in epidemiological studies.[63] EPEC requires at least 1 million organisms, and ETEC requires 100 million to 10 billion organisms to elaborate sufficient toxin to produce clinical effects.[64] Minimum inoculations of EAggEC and DAEC are not known.

CLINICAL RESPONSE

Enterohemorrhagic *Escherichia Coli*

Enterohemorrhagic *E. coli* is often used synonymously with *E. coli* serotype O157:H7. EHEC is a common cause of bacterial diarrhea, particularly in children under four years of age. The typical presentation of EHEC involves the initial onset of watery diarrhea followed by the development of severe, frequently bloody stools and abdominal cramps with mild or no fever. Infection with this strain is usually associated with hemorrhagic colitis despite the absence of bloody diarrhea in approximately 25% of recognized cases.[65] Rare case reports associate infection by *E. coli* serotype O157:H7 with ischemic pseudomembranous colitis.[66] The differential diagnosis for EHEC includes gastrointestinal hemorrhage, acute mesenteric infarction, intussusception, inflammatory bowel disease, intestinal polyps, Meckel’s diverticulum, and infectious enteritis (*Campylobacter*, *Salmonella*, *Shigella*). An asymptomatic carrier state can occur following the resolution of the gastrointestinal illness.

Hemolytic-Uremic Syndrome

Children with gastrointestinal exposure to EHEC may develop hemolytic-uremic syndrome, but this illness is rare in adults. In EHEC-induced hemolytic-uremic syndrome, 10% of cases do not develop initial gastrointestinal symptoms.[67] After an incubation period of 3–5 days, patients typically have an initial 3–4-day phase of watery diarrhea, dehydration, and severe cramps, followed by bloody diarrhea.[67] Vomiting and low-grade fevers occur occasionally. Gastrointestinal symptoms are self-limited, and usually resolve 1–14 days after the onset of symptoms. However, patients can shed EHEC for 1–2 weeks after symptoms resolve. In young children, 10–15% of cases progress to hemolytic-uremic syndrome, marked by the triad of microangiopathic thrombocytopenia, hemolytic anemia, and oliguric renal failure within 2 weeks of onset of diarrhea.[68] This illness is the most common cause of acute renal failure in children in the United States with up to 50% of these cases requiring dialysis. The mortality rate associated with hemolytic-uremic syndrome with intensive care is 3–5%.[68] In a meta-analysis of 3,476 patients (aged 1 month–18 years at the time of recruitment) in 49 studies, death or permanent end-stage renal disease (ESRD) ranged from 0–30% with a pooled incidence of 12% (95% CI: 10–15%).[69] Approximately 25% of survivors demonstrate long-term renal sequelae (proteinuria, decreased glomerular filtration rate). Eight to ten percent of patients with hemolytic-uremic syndrome develop complications including biliary lithiasis, colonic strictures, abdominal pain, hypertension, seizures, blindness, paralysis, and short-gut syndrome.[67,70] The clinical presentation, endoscopic findings, and histopathology of mucosal biopsies are identical to that of ischemic colitis. The differential diagnosis of hemolytic-uremic syndrome includes other infectious causes (non-O157 enterohemorrhagic *E. coli*, *Streptococcus pneumoniae*, *Salmonella* serovar Typhi, *Proteus* spp., and *Shigella* spp.), hemotoxic drugs (mitomycin, cyclosporin, tacrolimus), high-dose total body irradiation, and familial hemolytic-uremic syndrome associated with coagulation abnormalities.[71]

Thrombotic Thrombocytopenic Purpura

Case reports have associated EHEC with the development of thrombotic thrombocytopenic purpura (TTP) in adults.[72] The clinical presentation of TTP includes fever (60%), impaired renal function, and neurologic dysfunction (36%), as well as purpuric rash with thrombocytopenia and microangiopathic hemolytic anemia. However, not all signs are apparent on presentation. Splenomegaly, jaundice, and hypertension may also occur. Severe cases may proceed to develop seizures, hemiplegia, paresthesias, arthralgias, and abdominal pain. Mortality in the elderly following *E. coli*-induced TTP approaches 50%.

Enteropathogenic *Escherichia Coli*

EPEC causes mild, watery diarrhea after an incubation period of 9–24 hours.[40,73] Symptoms typically resolve

spontaneously within 1–7 days.[74] Prolonged diarrhea (i.e., <14 days) can occur in bottle-fed infants, with breast-feeding providing some protection.

Enteroinvasive *Escherichia Coli*

EIEC classically causes *Shigella*-like dysentery, but most often cause watery diarrhea followed by scant mucus-bloody stools 12–72 hours after ingestion.[65] Cramps, diarrhea, vomiting, fever, chills, tenesmus, and malaise are sometimes present, further mimicking shigellosis. Symptoms typically resolve spontaneously within 5–7 days.[43,73] An asymptomatic carrier state can occur following EIEC infection.

Enterotoxigenic *Escherichia Coli*

ETEC causes high-volume, cholera-like, watery diarrhea 14–72 hours after ingestion. Cramps are more common than in cholera. Diarrhea may be accompanied by low-grade fever, nausea, malaise, vomiting, headache, muscle aches, bloating, and loss of appetite. Symptoms are similar to a viral flu-like illness, and these symptoms typically resolve within 3–4 days.[75]

Enteroaggregative *Escherichia Coli*

EAggEC causes a persistent watery, secretory diarrhea in adults and children, lasting 14 days or longer. The incubation period lasts approximately 20–48 hours.[76]

DIAGNOSTIC TESTING

Analytical Methods

In food-processing practices, a selective differential medium called hemorrhagic colitis agar isolates EHEC from foods. This culturing process is limited, however, by the extended period of time necessary to identify pathogenic organisms. Newer techniques are being developed to accelerate identification times. Mulitplex polymerase chain reaction (PCR) detects multiple strains of *E. coli* and other pathogens in produce within 30 hours.[77] A multianalyte antibody-based dipstick prototype is under development, which can provide immediate detection of EHEC foods.[78] Genotyping with pulsed-field gel electrophoresis (PFGE) verifies slaughter hygiene in cattle.[79] Biomagnetic separation (BMS) uses paramagnetic microspheres coated with ligands that have a special affinity to specific microbes.[80] A novel test uses a silicone microcantilever that is coated with antibodies, and the resulting structure bends upon recognition of antibodies to *E. coli*.[81]

The self-limited course of most *E. coli*-related gastrointestinal diseases often limits the necessity of laboratory confirmation in the healthcare setting. Rapid assays for Shiga toxin-producing strains include enzyme-linked immunosorbent assay (ELISA) and enzyme-immunoassay (EIA). Because of false-positive results from these assays, confirmation and serotyping is necessary by stool culture and sorbitol-MacConkey agar analysis.[82] Cases of severe bloody diarrhea or dysentery may warrant testing for *E. coli* O157:H7, both for public health implications and for differentiation from other important bacterial causes of diarrhea such as *Salmonella* and *Shigella* spp. Currently, the US Center for Disease Control (CDC) recommends culturing all bloody stools with screening for EHEC. AOAC International (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) has at least 23 official methods of analysis for qualitative and quantitative determination of *E. coli* in various matrices (water, various foods) and for identifying serotype O157.[83] Table 17.1 lists some official methods for the analysis of *E. coli* in various matrices.

TABLE 17.1. Some Official Methods of Analysis of *Escherichia Coli* in Various Matrices as Listed by the AOAC International

Method	Matrix	AOAC Number
Microbiological	Fish/cooked seafood, meat and meat products/frozen cooked meat products, nuts and nut products/tree nut meats	966.23
Coliform and *Escherichia coli* counts in foods	Foods	991.14
Total coliforms in *Escherichia coli* in water	Water	991.15
Escherichia coli enterotoxins	Mouse/suckling mouse, mouse/mouse adrenal cell	984.35
Escherichia coli O157:H7 in selected foods	Meat and meat products/cooked beef, eggs and egg products/liquid eggs, meat and meat products, poultry products	996.09, 996.10, 2000.13, 2005.04
Enterotoxigenic *Escherichia coli*	Media	986.34

Enterohemorrhagic *Escherichia Coli*

Laboratory detection of *E. coli* O157:H7 is important for public health concerns to differentiate this *E. coli* strain from *Shigella* and for the monitoring of the development of hemolytic-uremic syndrome. The isolation of E. coli O157:H7 requires special media, and subtyping with PFGE allows the tracking of related infections for determination of the source of the infection. In suspected clinical cases of *E. coli* O157:H7 infection, all laboratory requests should ask specifically for *E. coli* O157:H7 detection because the isolation of this strain is not routine for all *E. coli* strains. All *E. coli* grow on lactose enriched MacConkey agar, forming pink colonies. Substitution of sorbitol for lactose singles out EHEC into nonpink islands because this strain does not ferment sorbitol. Tests are 92% positive in the first week of illness, but 33% positive thereafter, illustrating the benefit of early testing.[84] These colonies are then tested for O157 lipopolysaccharide antigen side chain by latex agglutination. Positive specimens are often referred to public health laboratories for H7 antigen detection.[85,86] Antibodies to *E. coli* secretory proteins are produced in the acute phase of EHEC infection, particularly in response to *EspB*. Detection of these antibodies in serum may be useful when fecal strains have not been isolated.[38,87] Multiplex PCR can rapidly identify *E. coli* O157:H7 in 24 hours, using antibodies to genes encoding for intimin and Shiga toxins. This method also differentiates O157:H7 from non O157:H7 isolates.[88] Multiplex PCR may be the broader alternative to conventional PCR restriction fragment length polymorphism because different genes can be amplified together in the same reaction. Thus, simultaneous detection of EHEC, EPEC, ETEC, and EIEC is possible.[89]

Enteropathogenic *Escherichia Coli*

Clinical laboratories do not routinely test for EPEC, though it can be identified by serologic and cultural assays from stool. A fluorescent-actin stain of *E. coli* isolates detects actin accumulation associated with EPEC A/E lesions.[90] PCR or multiplex PCR allow precise detection with close to 100% sensitivity.[91]

Enteroinvasive *Escherichia Coli*

Clinical laboratories do not routinely test for EIEC, but it can be detected by genetic probes for the enteroinvasiveness plasmid (similar to identification of *Shigella* spp.) or by demonstration of enteroinvasiveness in tissue culture (positive Seleny test). A novel monoclonal antibody blot immune assay can identify and differentiate EIEC from *Shigella* spp. quickly, thus enabling early decision-making on antibiotic use.[92] PCR is significantly more sensitive than culture for the detection of EIEC with a sensitivity of 96% and 54%, respectively.[93]

Enterotoxigenic *Escherichia Coli*

Clinical laboratories do not routinely test for ETEC, but the evaluation of foodborne outbreaks of gastroenteritis may require special testing. ETEC stool cultures show large numbers of fimbriae-expressing *E. coli*. Serotyping follows the isolation of *E. coli* by culture. PCR for genes coding enterotoxins and/or fimbriae improves the sensitivity of culture results. More advanced testing involves the inoculation of the isolates into tissue culture of mouse adrenal cells or Chinese hamster ovarian cells. The stimulation of adenylate cyclase by the heat-labile toxin (LT) produces positive results. ELISA can also detect the LT, and DNA probes can detect the gene sequence.[94]

Biomarkers

Biomarkers are not routinely used for the identification of specific toxins in clinical cases. Biomarkers are often used to provide reliable information on identification and classification of homologous clones for research purposes.[95]

Abnormalities

Fecal leucocytes commonly occur with EIEC and EHEC, but not generally with ETEC, EPEC, or EAggEC. Significant anemia (Hgb < 10) can develop during *E. coli*-induced hemorrhagic colitis secondary to blood loss. All strains can produce severe serum electrolyte abnormalities with a profile similar to that seen in dehydration from gastrointestinal fluid losses. Severe dehydration involves hypernatremia (serum Na > 150 mEq/L) or hyponatremia (serum Na < 130 mEq/L); hypokalemia (serum K < 3.0 mEq/L); hypochloremia, elevated urine specific gravity (SpG > 1.020); low serum bicarbonate secondary to lactic acid production, or elevated serum bicarbonate secondary to contraction alkalosis. Progression of laboratory abnormalities often requires inpatient hospital admission, particularly if the patient is not able to tolerate adequate oral fluid intake.

Both hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (TTP) are primarily clinical diagnoses, but several laboratory parameters help substantiate the diagnoses. In hemolytic-uremic syndrome, a complete blood count typically reveals low hemoglobin and hematocrit, resulting from acute, mechanical (Coombs-negative) intravascular hemolysis along with increased reticulocyte count, serum aspartate amino-

transferase, serum alanine aminotransferase, serum indirect bilirubin, and serum lactate dehydrogenase. Increased mean platelet volume reflects reduced platelet survival time secondary to increased platelet consumption. Giant platelets may also develop. Platelet count is usually less than 60,000 per mL. The hallmark of hemolytic-uremic syndrome is the presence of deformed, fragmented, or helmet-shaped red blood cells (i.e., schistocytes) on peripheral blood smear. Consumptive coagulopathy does not occur; therefore, coagulation parameters are within normal limits including prothrombin time (PT), activated partial thromboplastin time (aPTT), D-dimer, and fibrinogen. This feature differentiates both hemolytic-uremic syndrome and TTP from disseminated intravascular coagulation (DIC). The leucocyte count is sometimes mildly elevated, but rarely greater than 20,000 per mL. Serum globulin, complement, and albumin determinations are decreased.[67,96] Urine, if available, may contain protein, erythrocytes, hemoglobin, leucocytes, and casts.

As platelet microthrombi occlude the glomeruli, renal failure ensues with marked elevations in blood urea nitrogen (BUN) and serum creatinine. Urinalysis in oliguric patients typically demonstrates leucocytes, erythrocytes, protein, hemoglobin, and cellular casts.[67] Endoscopy, though rarely necessary, shows a pattern identical to ulcerative colitis, and abdominal ultrasound shows bowel wall edema and ascites. Thrombotic thrombocytopenic purpura causes a hemopathologic profile similar to hemolytic-uremic syndrome.

TREATMENT

Treatment of gastrointestinal manifestations of all strains of *E. coli* includes maintenance of fluid and electrolyte balance along with bowel rest. Laboratory confirmation of *E. coli* spp. is not usually available for several hours to days after clinical presentation. Therefore, supportive care should be directed at correction of dehydration; replacement of ongoing losses from stools and emesis; and blood transfusion if indicated. The use of antimotility agents, opioids, and anticholinergics should be avoided because these drugs may potentiate the pathogenicity of *E. coli* and predispose the patient to the development of hemolytic-uremic syndrome. Based on clinical similarities, suspected EIEC cases often cannot be differentiated clinically from shigellosis, and clinical experience suggests that the use of antimotility agents is contraindicated.[97]

Enterohemorrhagic *Escherichia Coli*

Although there are only limited data, antimicrobials are not usually recommended in cases of EHEC because of the perceived risks of increased Shiga-toxin production, the worsening renal injury, and the progression to hemolytic-uremic syndrome.[98] Previous clinical data on the treatment of EHEC with antibiotics suggest that antibiotic treatment had no statistically significant effect on the progression of symptoms, the excretion of fecal pathogen, or the incidence of hemolytic-uremic syndrome.[99] However, more recent prospective studies demonstrated an increased risk (RR = 14.3, 95% CI: 2.9–70.7) of this disease with antibiotic treatment in children with *E. coli* O157:H7.[98] Because the similarity in onset of bloody diarrhea during both *Shigella* and *E. coli* O157:H7 infections, antibiotic therapy with a second- or third-generation cephalosporin (e.g., ceftriaxone) is a potential option until stool cultures return. However, health departments typically serotype EHEC, and thus the definitive diagnosis is often delayed. Oral Shiga toxin-binding agents do not reduce the severity of the gastrointestinal illness in pediatric patients.[100]

In hemolytic-uremic syndrome, supportive treatment of hypertension, renal failure, and other complications is recommended. Fluid overload must be avoided, and early dialysis is often necessary for acute renal failure. Platelet transfusions should be avoided unless the patient has active bleeding because of the association between platelet transfusion and exacerbation of renal damage. Plasma exchange (plasmapheresis combined with fresh-frozen plasma replacement) is an option for severe cases of hemolytic-uremic syndrome. However, there are inadequate data to confirm the ability of plasma exchange to alter clinical outcome. Secretory immunoglobulin A (sIgA) prevents the attachment of enteropathogens to gut epithelium in newborn infants. Breast milk colostrum contains sIgA towards *EspA, EspB*, intimin, and Shiga toxins. Anti-*EspA* sIgA is produced in high quantities, offering a potential target for immunization and anti-toxin strategies in EHEC and EPEC.[101–104]

In TTP, aggressive supportive care of anemia and fluid imbalance is important, and fluid replacement with fresh frozen plasma may be necessary. Although corticosteroids frequently are administered, there are inadequate data to determine whether the use of corticosteroids alters clinical outcome. Case reports suggest that the use of antiplatelet drugs improves renal function, but there are inadequate data at the present time to support the efficacy of this treatment, and these agents may increase the risk of hemorrhage.[105] Platelet infusion is contraindicated because of an association with worsening platelet aggregation seen in postmortem examination of the CNS of these patients. Some patients benefit from splenectomy in severe cases. Refractory cases have been treated with vincristine, with an unknown mechanism of action.[106] Hemodialysis may be

required for renal failure. The use of plasmapheresis for *E. coli*-associated TTP has not altered clinical outcome in pregnant patients or in patients with cancers or HIV infection.[106]

Enteropathogenic *Escherichia Coli*

Treatment of EPEC is entirely supportive. The use of antibiotics during EPEC infection has not improved clinical outcome.[107]

Enteroinvasive *Escherichia Coli*

EIEC is a self-limited disease that does not require antimicrobial therapy, although antibiotics are often administered because of suspected *Shigella* infection. Empiric antibiotic use did not worsen the clinical syndrome of EIEC in case reports.[108] Supportive treatment recommendations are identical to those proposed for shigellosis, and the initial use of antibiotics is reasonable, based on the clinical similarities between EIEC and *Shigella*-induced dysentery. When laboratory evaluation rules out *Shigella* species, antibiotics may be discontinued. No controlled trials have examined the efficacy of antimicrobial therapy in EIEC infections, but case reports suggest the use of trimethoprim-sulfamethoxazole, fluoroquinolones, and ciprofloxacin shortens the duration of disease. The lack of consistent efficacy is likely due to significant antibiotic resistance.[109]

Enterotoxigenic *Escherichia Coli*

ETEC responds very well to supportive care, and most cases do not require hospitalization. Antibiotics are not generally recommended, but fluoroquinolones, tetracycline, and trimethoprim-sulfamethoxazole have reduced the duration of symptoms in limited trials. Significant resistance to antibiotics is likely responsible for the lack of consistent therapeutic efficacy.[110] Breast milk confers passive immunity to infants via immunoglobulins, and breast milk also contains receptor molecules that neutralize *E. coli* toxins and colonization-factor antigens. Bismuth salicylate may provide symptomatic relief of both cramping and stool frequency.[45]

Chapter 18

LISTERIA MONOCYTOGENES

CYRUS RANGAN, MD, FAAP

HISTORY

Listeria monocytogenes (Murray et al.) Pirie (*L. monocytogenes*) is a gram-positive, facultatively anaerobic, catalase-positive, motile coccobacillus. This organism was first cultured in 1921 by French microbiologists Jérôme Dumont and Louis Cotoni at L'Institut Pasteur de Paris, France, and named for British surgeon Lord Lister.[1] In 1926, Murray et al. first reported the occurrence of listeriosis in rabbits.[2] The first documented outbreak of foodborne listeriosis occurred in 23 patients at a Boston hospital in 1979, and definitive proof of the foodborne transmission of human listeriosis was first reported in 1983.[3] Most exposures of healthy individuals to *L. monocytogenes* do not produce symptoms, and up to 10% of healthy individuals harbor *L. monocytogenes* in the gastrointestinal tract. In the United States, approximately 2,500 cases of listeriosis are confirmed annually with a mortality rate of 20–30%. This mortality rate is the highest mortality rate of all foodborne bacterial infections.[4]

EXPOSURE

Source

ENVIRONMENT

Listeria species are tolerant to extreme salt, temperature, and pH. These organisms are ubiquitous in soil, water, fertilizers, and effluents worldwide. These organisms proliferate readily on decomposing vegetation.[5,6] *Listeria* species occur in the feces of 1–5% of healthy individuals, particularly nonpathogenic species (e.g., *L. innocua*).[7] However, there are inadequate data to distinguish between a carrier state and transient passage of these bacteria due to environmental exposures.

ANIMAL

Listeria monocytogenes is widely distributed in nature including domestic and wild animals, water soil, and plant materials. Humans, ruminant animals, and fowl carry *L. monocytogenes* asymptomatically.[8] However, most strains in animals are not pathogenic in humans.[9] Pregnant females may transmit infections vertically to fetuses or neonates.[10] Healthcare providers may prevent rare nosocomial transmission of *L. monocytogenes* in the neonatal inpatient setting via hand washing and utilization of 70% ethanol antiseptic gels.[11]

FOOD

Listeria monocytogenes occurs in a wide variety of foods including prepared, ready-to-eat, refrigerated foods, (e.g., turkey deli meats, sliced ham, pâtés, hot dogs, sausages), soft cheeses, coleslaw, undercooked chicken, leafy vegetables (lettuce, carrots), and dairy products (e.g., contamination of pasteurized milk).[12–15] Although *L. monocytogenes* is present in meat, poultry, diary, and vegetables, contamination levels are typically low and human listeriosis is relative rare.[16] In a study of Italian

TABLE 18.1. *Listeria Monocytogenes* Serogroups Identified in 167 Strains Isolated from Retail Foods in Florida and Greater Washington, DC

Serotypes	% Serotypes
1/2b, 3b	41
4b, 4d, 4e	32
1/2a, 3a	26
1/2c, 3c	1.2
4a, 4c	0.6

Source: From Ref 20.

dry sausage, 22.7% of the samples contained detectable amounts of *L. monocytogenes* (1/2c, 1/2a, 1/2b, 4b), but the contamination levels were below 10 CFU/g.[17] Shelf-stable forms of these foods harbor substantially lower rates of *L. monocytogenes*. The bacteria proliferate particularly well at the pH range of unpasteurized soft cheeses (pH 5.2–6.4).[18] There are at least 13 serotypes of *L. monocytogenes* with serotype 1/2a being the most prevalent serotype in food.[19] Table 18.1 lists the serogroups found in 167 isolates of *L. monocytogenes* from retail foods including ready-to-eat meats, raw chicken carcasses, and fresh produce.[20]

Although *L. monocytogenes* is ubiquitous, most human outbreaks of foodborne listeriosis involve a small number of closely related strains, particularly two clonal groups (epidemic clone [EC] I and II) of serotype 4b.[21,22] The genomic diversity is higher among the strains with ECII-like characteristics than among those strains carrying the ECI-specific genetic markers.[23]

Food Processing

The ability of *L. monocyto*genes to proliferate under relatively dry, refrigerated conditions enhances contamination of food by these bacteria.[24] The most effective means to control *L. monocytogenes* include the following: proper cooking and refrigeration; pasteurization of dairy products; separation of cooked and uncooked foods; sanitation of food preparation surfaces with at least 1% bleach solution; and washing of vegetables.[25] *L. monocytogenes* survives in environments of up to 20% NaCl. Hence, refrigeration or the addition of salt does not effectively control the growth of *L. monocytogenes*.[26] Freezing temperatures (<–20°C/–4°F) and high pressures effectively limit *L. monocytogenes* growth.[27,28] Cooking foods to 120°C –170°C (248°F–338°F) also kills this bacteria; however, a significant portion of *L. monocytogenes* exposures result from the consumption of refrigerated, ready-to-eat foods that do not require cooking.[29]

TOXINS

Physiochemical Properties

The genus *Listeria* contains eight species (*L. agrestis, L. grayi, L. innocua, L. ivanovii, L. monocytogenes, L. murrayi, L. seeligeri, L. welshimeri*), which are gram-positive, nonspore-forming, rod-shaped, facultative anaerobes. Only *L. monocytogenes* and *L. ivanovii* are pathogenic with the latter species being primarily an animal and, rarely, a human pathogen.[30] *L. monocytogenes* is morphologically indistinguishable from other *Listeria* species, and these bacteria are divided into at least 13 serovars based on unique combinations of somatic (O) and flagellar (H) antigens. Serovars 4b, 1/2b, and 1/2a are the main serovars causing human disease with the latter two serovars being responsible primarily for sporadic cases of human listeriosis. Other serovars of *L. monocytogenes* cause disease in animals or are nonpathogenic.[31] *L. monocytogenes* grows over a wide temperature range (1°–45°C/34°F–113°F), and thus proliferates under refrigeration (0°C–4°C/32°F–39°F), at room temperature (20°C–25°C/68°F–77°F), and at human body temperature (37.0°C/98.6°F). This organism thrives in high salinity conditions, (e.g., bile salts in the intestines). *L. monocytogenes* grows at pH 4.4 to 6.0 with survival at pH 3.6 to 9.5.[32] Gastric acid kills *L. monocytogenes*, and patients ingesting medication causing decreased gastric acidity may be at higher risk for *L. monocytogenes* infection.[33,34]

Mechanism of Toxicity

Listeria monocytogenes is a facultative intracellular bacterium, which can invade and multiply in both phagocytic and nonphagocytic cells. This pathogen has the ability to cross intestinal, placental, and blood–brain barriers, producing local infections. The entry of this pathogen into human cells results from a species-specific interaction of a surface protein, internalin, with the human receptor, E-cadherin. *L. monocytogenes* can synthesize flagella at 20°C–25°C (68°F–77°F), but not at human body temperature (37.0°C/98.6°F); thus, *L. monocytogenes* motility relies on a characteristic tumbling motion that counters the flow of peristalsis, permitting prolonged transit through the gastrointestinal lumen.[35,36] Several factors are responsible for the infection of human cells by *L. monocytogenes* including the following: 1) internalin (InlA, InlB) causes the internalization of the bacteria into the cell, 2) listeriolysin along with two phospholipases (PlcA, PlcB) allow the escape of the bacteria from phagocytes, and 3) ActA mediates the actin-based intracellular and extracellular movement of the pathogen. The prominence of factors (e.g.,

internalin in serotype 4b) accounts for the prevalence of this serotype in human listeriosis.[37] *L. monocytogenes* adheres to enterocytes and intestinal macrophages via D-galactose residues on the bacteria surface.[38] Internalin protein, AnlA, on the bacterial cell wall binds to the transmembrane glycoprotein E-cadherin on the mucosal surface of polarized epithelial cells. Connected directly to the actin cytoskeleton, E-cadherins are associated with two adjacent surface proteins, myosin VIIa and vezatin that mediate enterocytic phagocytosis of *L. monocytogenes*.[39,40] Another invasion protein, InlB, uses the signalling pathway of the hepatocyte growth factor receptor, Met, to induce endocytosis of the receptor and the internalization of the bacteria into nonpolarized cells (e.g., hepatocytes, fibroblasts, epithelioid cells).[41] *L. monocytogenes* escapes the highly oxidative and acidic environment of the phagosome by producing catalase, superoxide dismutase, and two hemolysins (listeriolysin O, phospholipase C). These hemolysins lyse the phagosome and allow *L. monocytogenes* to proliferate in the cytosol.[42,43] The listeriolysin-encoding gene (hlyA) occurs only in virulent strains of *L. monocytogenes*.[44] After lysis of the primary vacuoles, *L. monocytogenes* grows and multiplies in the cytosol. The intracellular mobility and cell-to-cell spread of this bacteria depends on another *L. monocytogenes* cell wall surface protein, ActA. This 67kDa protein reorganizes the enterocytic actin cytoskeleton into rope-like polymers, which punch pocket-like filopods along the enterocytic inner membrane.[45] These Act A-bound actin polymers thrust microcolonies of *L. monocytogenes* into the filopods, thus propelling the filopods into adjacent enterocytes.[46] Adjacent enterocytes subsequently engulf protruding filopods, thus permitting *L. monocytogenes* to pass safely into new enterocytes, where they continue to proliferate while evading host immune defenses.[47] Because epithelial cells, M cells, and macrophages are rarely destroyed by *L. monocytogenes*, enteric macrophages readily transport *L. monocytogenes* to the liver and spleen.[48] *L. monocytogenes* subsequently induces phagocytosis in parenchymal cells of the liver and spleen, where they proliferate further before disseminating to other locations, particularly the central nervous system.[49] Bacterial uptake into brain parenchymal cells and the meninges causes infection of the central nervous system. T-cells, natural killer cells, interferon-gamma, and interleukin-18 prevent extraintestinal manifestations of *L. monocytogenes* in most healthy individuals.[50] In utero, *L. monocytogenes* invades placental endothelial cells in similar fashion, resulting in premature labor, fetal death, or perinatal listeriosis.[10] Both underdeveloped fetal immune system and two-way transfer of *L. monocytogenes* between the placenta and maternal organs increase the fetal risk of listerosis during pregnancy.[51]

DOSE RESPONSE

The current US standard for *L. monocytogenes* content in food is zero, but the European Union and Canada allow 100 CFU/g for ready-to-eat foods unable to support the growth of these bacteria. The infective dose of *L. monocytogenes* in healthy persons is unknown, and these individuals do not typically manifest clinical symptoms.[52] The estimated average median dose of these bacteria in healthy individuals, who developed fever and diarrhea after ingesting contaminated chocolate milk, was 2.9×10^{11} CFU.[53] In susceptible populations, fewer than 1,000 organisms may cause gastrointestinal or systemic disease. High-risk populations include pregnant woman, fetuses, neonates, elderly individuals, immunocompromised patients, steroid-dependent patients, and patients with decreased gastric acidity. Pregnant women in the third trimester of pregnancy are infected at a rate 20 times that of the general population, secondary to impaired cell-mediated immunity.[10] Immunocompromised patients are infected at a rate 300 times that of the general population.[52] The overall mortality rate of listerosis is 20–30%, but this rate reaches 60% in patients with central nervous system disease, and 50% in cases of newborn listeriosis.[4,54]

CLINICAL RESPONSE

Listeria monocytogenes incubates for 1–2 days before gastrointestinal symptoms occur. A latency period of 3 days to 10 weeks occurs before systemic listeriosis appears. In healthy individuals exposed to foods containing high concentrations of *L. monocytogenes*, classic foodborne listeriosis begins with an asymptomatic infection or by a mild, self-limited flu-like illness manifest by fever, malaise, nausea, vomiting, diarrhea, and myalgias.[55] The gastroenteritis occurs without symptoms of bacteremia or more serious infections. However, in susceptible patients, systemic invasion leads to septicemia and/or meningoencephalitis with clinical effects including headache, photophobia, stiff neck, ataxia, and alteration of mental status.[56] Seizures occur in 25% of cases with nervous system involvement.[57] Pregnant woman may spread *L. monocytogenes* vertically after asymptomatic or symptomatic infection, inducing premature labor, miscarriage, stillbirth, and neonatal listeriosis. Neonates may become infected via multiple routes including in utero, contact with vaginal fluid during birth, contact with maternal shedding up to 10 days after delivery, and following consumption of contaminated breast milk.[10] Neonates may be asymptomatic for up to 8 weeks before developing systemic manifestations, including septicemia, meningitis, disseminated granulomatosis, or pneumonia.[58] Meningitis, meningoencepha-

litis, and rare cases of brain abscess and endocarditis occur following *L. monocytogenes* infections, primarily in elderly and immunocompromised patients.[59,60] Infected or colonized patients may shed bacteria in feces for several months.[61]

DIAGNOSTIC TESTING

Analytical Methods

Biochemical methods of identifying *L. monocytogenes* involve isolation with selective and enrichment media, followed by Gram stain and multiple biochemical tests. *L. monocytogenes* is gram-positive; however, Gram staining alone is only 60% specific for *L. monocytogenes*. These bacteria may be coccoidal, resembling *Streptococcus*, or rod-shaped, resembling *Corynebacteria*.[57] The characteristic features of *L. monocytogenes* are a tumbling motion under light microscopy similar to *Vibrio* species, the production of hemolysins (listeriolysin O, phospholipase C), and the presence of flagellae at room temperature.[35,36] Laboratories must be specifically advised to evaluate for *L. monocytogenes* in suspected specimens because conventional methods for the detection of foodborne bacterial pathogens rely on the use of selective microbiological media (e.g., FDA enrichment broth). Specimens from blood, cerebrospinal fluid, aborted fetuses, or placentas must be cold-enriched at 4°C (39°F) for 28–72 hours before culturing on chromogenic agar, where colonies display a turquoise hue (sensitivity 85.7%, and specificity 100%).[62] *Corynebacteria* also grow under similar laboratory conditions. Stool cultures are not utilized to detect listerosis because of the high rates of asymptomatic carriage of *L. monocytogenes* species.[61] Cultured colonies of *L. monocytogenes* exhibit a weak zone of β-hemolysis after streaking onto sheep blood agar.[63]

DNA-based methods allow the amplification of specific genetic signals from a few cells, and therefore these analytical methods are much more sensitive and specific than the use of selective microbiological media.[44] Polymerase chain reaction (PCR) is the basis of many nucleic acid-based detection systems. This method detects both live and dead strains of *L. monocytogenes*, and PCR for this bacteria yields 99% specificity and 100% sensitivity.[64] PCR after immunomagnetic separation is a sensitive method for detecting *L. monocytogenes* in food samples at concentrations >100 CFU/g, but the detection of lower concentrations of these bacteria requires the use of enrichment broth.[65] Subtyping procedures are useful for tracking individual strains responsible for outbreaks of listeriosis. Analytical methods for subtyping include phenotypic subtyping (serotyping, phage typing, multilocus enzyme electrophoresis, esterase typing) and genotypic subtyping (pulsed-field gel electrophoresis, ribotyping, PCR-based subtyping techniques, amplified fragment length polymorphism, PCR-restriction fragment length polymorphism, repetitive element PCR, DNA sequencing-based subtyping techniques, such as multilocus sequence typing). These subtyping techniques are reserved for the investigation of epidemics.[66]

There are 13 different AOAC International (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) official methods of analysis for *L. monocytogenes* in foods.[67]

1. Methods 992.18: A qualitative biochemical identification method for *L. monocytogenes* species in foods
2. Method 992.19: A qualitative biochemical identification method for *L. monocytogenes* species in foods
3. Method 993.09: A qualitative colorimetric DNA hybridization method for dairy products, seafoods, and meats. (The rest of the official methods utilize commercially available test kits)
4. Method 993.12: A qualitative selective enrichment and isolation method for *L. monocytogenes* in milk and dairy products
5. Method 994.03: A qualitative colorimetric monoclonal enzyme-linked immunosorbent assay method for determination of *L. monocytogenes* in dairy products, seafoods, and meats
6. Method 995.22: A qualitative colorimetric polyclonal enzyme immunoassay screening method for *L. monocytogenes* in foods
7. Method 996.14: A polyclonal enzyme immunoassay for *L. monocytogenes* and related species in selected foods, including dairy products, vegetables, fruits and fruit products, red meats, pork, pasta, cacao bean and its products, and eggs and egg products
8. Method 997.03: A qualitative visual immunoprecipitate assay for *L. monocytogenes* and related species in selected foods, including dairy products, vegetables, fruits and fruit products, red meats, pork, pasta, fish, and eggs and egg products
9. Method 999.06: A qualitative enzyme-linked immunofluorescent assay for *L. monocytogenes* in foods
10. Method 2002.09: A qualitative colorimetric polyclonal enzyme immunoassay screening method for *L. monocytogenes* in foods
11. Method 2003.12: A qualitative PCR method for *L. monocytogenes* in foods

12. Method 2004.02: A quantitative instrumental method for determination of *L. monocytogenes* in foods
13. Method 2004.06: An automated enzyme-linked fluorescent immunoassay for the detection of *L. monocytogenes* in dairy products, vegetables, seafood, raw meats and poultry, and processed meats and poultry

Biomarkers

Maternal fever around the time of delivery is a nonspecific sign of threatened perinatal bacterial infection. There is no biomarker for screening for *L. monocytogenes* during pregnancy; however, gram-positive stains of amniotic fluid in febrile patients with preterm labor may suggest *L. monocytogenes* infection.[68]

Abnormalities

Listeria monocytogenes elicits a marked monocytosis in animals, but rarely in humans.[57] Cerebrospinal fluid demonstrates a pleocytosis with moderately elevated protein and normal-to-low glucose.[69] Severe dehydration involves hypernatremia (serum Na > 150 mEq/L) or hyponatremia (serum Na < 130 mEq/L), hypokalemia (serum K < 3.0 mEq/L), hypochloremia, elevated urine specific gravity (SpG > 1.020), and hyperphosphatemia. Low serum bicarbonate results from lactic acid production or elevated serum bicarbonate secondary to contraction alkalosis.

TREATMENT

Treatment of *L. monocytogenes* infection includes bowel rest and rehydration with fluid and electrolytes replacement. Oral replacement may be sufficient, but affected patients may experience significant anorexia, necessitating intravenous fluid replacement and hospitalization in cases of significant dehydration or severe electrolyte abnormalities, particularly in young children or elderly patients.[70,71] Most gastrointestinal effects and associated flu-like symptoms rarely require hospitalization, and these effects resolve spontaneously in 1–2 days.[72] In cases of severe systemic listeriosis, prompt, early antimicrobial treatment is paramount. Virtually all human pathogenic *L. monocytogenes* organisms are susceptible to penicillin and its close derivatives (e.g., ampicillin, amoxicillin). Patients with confirmed or suspected listeriosis with extraintestinal manifestation should receive penicillin or a derivative until antimicrobial susceptibilities have been determined.[73] Therapy should continue for 4–6 weeks; however, patients with brain abscess or endocarditis may require a longer course of therapy.[74] Piperacillin, azlocillin, carbenicillin, and ticarcillin demonstrate intermediate antimicrobial activity against *L. monocytogenes*.[75] Penicillin-allergic patients may be placed on erythromycin or clarithromycin.[76] For immunocompromised patients, imipenem is a useful agent with a historically lower minimum inhibitory concentration than penicillin and broader coverage against other opportunistic organisms that threaten such patients.[77] Vancomycin is another alternative for immunocompromised patients; however, resistant *L. monocytogenes* strains are increasingly documented.[78] *L. monocytogenes* is resistant to cephalosporins, secondary to a wealth of penicillin-binding protein 3 to which cephalosporins bind poorly.[79] *L. monocytogenes* is also resistant to nalidixic acid and ofloxacin, and this organism is intermediately susceptible to levofloxacin, ciprofloxacin, and chloramphenicol.[80] Bacteriostatic activity of trimethoprim-sulfamethoxazole is not effective *in vivo*, secondary to rapid intracellular proliferation of *L. monocytogenes*.[80] Gentamicin is highly bacteriocidal, but this antibiotic is ineffective as a single agent because of the rapid transport of gentamicin into cellular lysosomes, where inactivation and limited contact with *L. monocytogenes* in the cytosol occurs. However, ampicillin plus gentamicin is a proven synergistic combination.[81]

Chapter 19

SALMONELLA

Cyrus Rangan, MD, FAAP

HISTORY

During the late 1800s to the mid-1900s, *Salmonella* serovar Typhi (*Salmonella* Typhi) was the leading cause of salmonellosis in the United States, but by the 1950s improvements in sanitation nearly eliminated typhoid fever. Now nontyphoidal *Salmonella* infections are more common than typhoid.[1] Antibiotics were introduced into the practice of veterinary medicine during the 1940s and into animal husbandry as feed additives to promote faster growth of livestock and domestic fowl during the 1950s.[2] In England and Wales during the 1960s, drug-resistant strains of *Salmonella* (*Salmonella typhimurium* phage type DT 29, DT204, DT 193, DT203c) appeared in cattle.[3] During the 1980s and 1990s, *Salmonella* serovar Enteritidis (*Salmonella* Enteritidis) emerged as an important contaminant of raw and undercooked chicken eggs.[4] The incidence rate for isolates of this serovar peaked in 1996 at 3.6 per 100,000 persons, and the rate declined at the end of the 1990s to about 2 isolates per 100,000 persons.[5] During this period changes in meat- and poultry-processing mandated by the Pathogen Reduction and Hazard Analysis and Critical Control Points (HACCP) rule of the US Department of Agriculture occurred. The fraction of *Salmonella* serovar Typhimurium (*Salmonella* Typhimurium) isolates with multidrug resistance increased substantially in the 1990s, primarily as a result of the epidemic spread of DT104.[6] By 1997, *Salmonella* Typhimurium again replaced *Salmonella* Enteritidis as the most common serovar in *Salmonella* enterocolitis.[7] Rodents are an important animal reservoir for *Salmonella* Enteritidis. During the late 1800s and early 1900s, *Salmonella* Enteritidis was used as a rodenticide, including use during outbreaks of *Yersinia pestis* (Lehmann and Neumann) van Loghem. This use was banned in the United States during the 1920s and in the United Kingdom and Denmark during the 1960s.[8] *Salmonella*-based rodenticides are still used in some countries with the phage type being similar to past strains of *Salmonella* that caused human illness and fatalities.[9]

EXPOSURE

Nomenclature

Officially, the *Approved Lists of Bacterial Names* identifies the genus *Salmonella* as containing the following five species: *Salmonella arizonae, Salmonella choleraesuis* (type species of the genus), *Salmonella enteritidis, Salmonella typhi* and *Salmonella typhimurium*.[10] However, DNA relatedness studies indicate that strains from all five of these species form a single DNA hybridization group with seven phenotypically different subgroups.[11] Based on Judicial Opinion 80 from the Judicial Commission of the International Committee on the Systematics of Prokaryotes and recent publications, the most common nomenclature for the genus *Salmonella* consists of the following names: *Salmonella bongori*, a relatively new species, *Salmonella subterranea*, and *Salmonella enterica* including *Salmonella enterica* subsp. *arizonae, Salmonella enterica* subsp. *diarizonae, Salmonella enterica* subsp. *enterica, Salmonella enterica* subsp. *houtenae, Salmonella enterica* subsp. *indica*, and *Salmonella enterica* subsp. *salamae*.[12] The subspecies, *S. enterica* subsp. *enterica* (synonym: *Salmonella choleraesuis* subsp.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

choleraesuis) contains over 99% of human isolates.[13] Each of the subspecies of *Salmonella enterica* (*Salmonella choleraesuis*) has serovars. Serovars are not species and therefore the serovar names are not italicized. To avoid confusion between serovars and species, the names of serovars are printed in Roman type starting with a capital letter. Although the names of some serovars denote a syndrome or host specificity (e.g. *Salmonella* Typhi, *Salmonella* Abortusequi), most recent serovars are named for the geographical origin of the first strain of the serovar (e.g., London, Panama). Consequently, simplified nomenclature for *Salmonella enterica* subsp. *enterica* serovar Typhi is *Salmonella* Typhi (typhoid fever). There are over 2,500 *Salmonella* serovars.[14] According to the International Code of Nomenclature of Bacteria (1990 Revision), the term serovar is preferred to the term serotype.[15] The shortened nomenclature prohibits abbreviation of the name of the genus (*Salmonella* = *S*.) because the abbreviation of a name of a genus is only authorized when followed by the name of a species.

Source

The vast majority of cases of salmonellosis result from animal to human transmission via food, and S*almonella* strains remain the most common cause of food poisoning among confirmed isolates of nine common enteric pathogens in the United States followed by *Campylobacter* and *Shigella*.[16] Most of the identified cases of *Salmonella* involve sporadic outbreaks of strains of *Salmonella enterica* subsp. *enterica* in single individuals rather than in several persons sharing a common meal.[17] Common serovars involved in human disease include *Salmonella* Choleraesuis (serovar rather than species), *Salmonella* Derby, *Salmonella* Enteritidis, *Salmonella* Infantis, *Salmonella* Muenchen, *Salmonella* Panama, *Salmonella* Typhimurium, and *Salmonella* Virchow. Other less common serovars include *Salmonella* Newport and *Salmonella* Heidelberg. The serovars *Salmonella* Typhi (typhoid fever) and *Salmonella* Paratyphi are highly adapted to humans and these serovars do not have other natural hosts, whereas *Salmonella* Typhimurium and *Salmonella* Enteritidis invade a broad range of hosts. Rodents are an important reservoir of *Salmonella* Enteritidis, particularly in poultry farms.

Animal

Salmonella enterica (*S. choleraesuis*) is a ubiquitous organism, particularly in the intestines of kittens, hedgehogs, birds (pet chickens, ducklings), pet rodents (hamsters, mice, rats),[18,19] and reptiles (lizards, snakes, turtles, crocodiles, kangaroo).[20–22] Pet ducklings are a source of *Salmonella* enterocolitis (*Salmonella* Hadar),[23] and small pet turtles harbor rare *Salmonella* serovars (e.g., *Salmonella* Pomona) pathogenic to humans, especially infants and children <5 years of age.[24,25] Approximately 7% of the cases of salmonellosis are attributed to pet reptile or amphibian contacts, and these infections usually involve relatively rare *Salmonella* serovars (e.g., Abaetetuba, Carrau, Chameleon, Ealing, Flint, Marina, Java, Kintambo, Poona, Stanley, Wassenaar).[26,27] Common serovars in food processing facilities include the following: broiler plants—*Salmonella* Kentucky, *Salmonella* Heidelberg; turkey plants—*Salmonella* Hadar, *Salmonella* Heidelberg; and swine plants—*Salmonella* Derby, *Salmonella* Typhimurium.[28] Although egg farms contain a variety of *Salmonella* serovars (*Salmonella* Pullorum, *Salmonella* Gallinarum, *Salmonella* Heidelberg), *Salmonella* Enteritidis is the only human pathogen that routinely contaminates chicken eggs.[29]

Food

Foods contaminated by *Salmonella* strains usually appear and taste normal. Sources of salmonellosis include contamination or cross-contamination of raw or undercooked eggs,[30,31] alfalfa sprouts (*Salmonella enterica* subsp. *enterica* serovars Newport, Stanley, Kottbus),[32–34] cantaloupe,[35] peanut butter,[36] undercooked meat (beef, pork),[37,38] poultry products,[39] unpasteurized milk[41,41] and dairy products (e.g., unpasteurized ice cream, cheese).[42] Shell eggs are an important source of *Salmonella* Enteritidis-induced enterocolitis.[43,44] Potential sources of salmonellosis from food containing raw eggs include homemade eggnog or ice cream, hollandaise sauce, cold deserts, and Caesar salad dressing. Commercial eggnog does not contain clinically significant numbers of *Salmonella* species because of the use of pasteurized eggs. *Salmonella* species occur most often on the shell of the egg as a result of fecal contamination. Internal contamination of the egg occurs from transmission of the bacteria through the shell (e.g., damp or contaminated environment) or transovarially during the formation of the yolk in the ovary or oviduct of an infected hen.[17] The ingestion of unpasteurized milk is a major risk factor for the acquisition of *Salmonella* Dublin infection.[45] Freshly cooked eggs do not usually cause *Salmonella* enterocolitis because the infective dose is low, unless the yolk is inadequately heated. Cross-contamination of food (spices, shellfish) and food contact surfaces by poultry carcasses[46] or infected food handlers[47] may cause outbreaks of *Salmonella* food poisoning. Other less common sources of Salmonella include lettuce, uncooked tomatoes,[48] cantaloupe (*Salmonella* Poona, *Salmonella* Saphra),[49] and cilantro.[50]

Food Processing

Although temperatures as low as 60°C (140°F) kill *Salmonella* bacteria in free egg fluid within a few minutes, light cooking does not eliminate *Salmonella* from the interior of the egg. Cooking must completely coagulate both the white and yolk to ensure the destruction of viable bacteria.[51] Antibiotic resistance in strains of *Salmonella* is chromosomally mediated, and proper cooking techniques (e.g., pasteurization) destroy these strains of *Salmonella* in a manner similar to that for less resistant strains.[52] *Salmonella* can survive refrigeration temperatures in an acidic environment, such as unpasteurized orange juice, for sufficient time to cause enterocolitis.[53] Table 19.1 lists recommendations for storage, cooking, and serving techniques that reduce the incidence of salmonellosis associated with the consumption of eggs.

TOXINS

Physiochemical Properties

Large numbers of *Salmonella* are usually required to cause invasion of the large- and small-bowel mucosa.[54] *Salmonella* species excrete a heat-labile enterotoxin that directly stimulates the adenylate cyclase-cAMP system causing secretion of chloride ions and inhibition of sodium absorption from the intestines.

Mechanism of Toxicity

Although the *Salmonella* enterotoxin potentially can increase the secretion of an isotonic load into the intestines, there are few data to support this mechanism as the cause of diarrhea during human infections. Instead, these organisms produce an inflammatory diarrhea by invading the mucosa. *In vitro* studies suggest that an invasion-associated type III export system (encoded on *Salmonella* pathogenicity island 1) facilitates tissue invasion and triggers an inflammatory response that produces fluid accumulation and leukocyte influx.[55] The distal ileum probably is the portal of entry. In the mouse model, M cells located in the follicle-associated epithelium in the Peyer's patches are the primary intestinal epithelial cell type invaded by *Salmonella* in a process that morphologically resembles phagocytosis.[56] In most cases, the organisms remain in the intestine and the infection is localized and self-limited. Occasionally, an initial bacteremia causes the seeding of infectious foci distant to the gastrointestinal tract. The production of

TABLE 19.1. Recommendations for the Use of Eggs by Consumers

Storage:
- Use grade A or AA eggs that have been properly refrigerated (≤45°F/7°C), clean, and are not cracked during storage prior to purchase.
- Refrigerate eggs (<40°F/4°C) in original container as soon as possible after purchase.
- Washing eggs prior to storage is not necessary.
- Rotate eggs so that the oldest egg is used first.
- Use shell eggs within 2–3 weeks of purchase, yolks and egg whites within 4 days, and boiled eggs within one week.
- Refrigerate leftover cooked egg dishes and use within 3–4 days.
- Liquid, frozen, and dried eggs and egg products should be pasteurized.
- Freeze eggs without the shell and use frozen eggs within one year.
- Cooked eggs for a picnic should be packed in an insulated cooler with adequate amounts of ice or frozen gel packs.

Cooking:
- Cook (≥145°F/63°C for ≥15 seconds) eggs thoroughly until both yolk and white are firm. Casseroles and other egg-containing dishes should be cooked to at least 160°F/71°C, documented by a thermometer.
- Use pasteurized eggs rather than raw eggs in recipes that recommend raw eggs (Caesar salad, mayonnaise, ice cream, hollandaise sauce, and homemade eggnog).
- Wash hands, equipment, utensils, and work surfaces with hot, soapy water after contact with raw eggs.

Serving:
- Serve cooked eggs and egg-containing foods immediately after cooking or cooled to room temperature (70°F/21°C) within 2 hours and from room temperature to refrigeration (41°F/5°C) within an additional 4 hours.
- Refrigerate or reheat cooked eggs if the food sits at room temperature for <2 hours.
- Eggs and egg dishes (soufflés, quiches) should be reheated to 165°F (74°C) before serving if refrigerated.
- Susceptible individuals (infants, elderly, immunocompromised persons) should avoid eating raw or undercooked eggs (pasteurized egg products are appropriate substitutes).

Source: Adapted from Ref 5.

bacterial stress proteins can also produce postinfection inflammatory sequelae.

DOSE RESPONSE

In general, large numbers of *Salmonella* organisms are necessary to cause gastrointestinal illness because *Salmonella* is heat labile and acid labile in stomach fluid. A variety of factors affect the infectivity rate including the dose of the organism, the complex interaction of host resistance (e.g., fatty vehicles, achlorhydria, antacid use, state of health, age), and the virulence of the organism. *Salmonella* Typhi has a much lower minimum infective dose compared with other serovars (*Salmonella* Enteritidis, *Salmonella* Pullorum) that are not adapted to humans.[57] In an experimental study of volunteers from a penal institution using a variety of *Salmonella* serovars (*Salmonella* Anatum, *Salmonella* Bareilly, *Salmonella* Derby, *Salmonella* Meleagridis, *Salmonella* Newport, *Salmonella* Pullorum, *Salmonella* Typhi), the minimum infective dose exceeded 10^5–10^7 organisms.[58–60] Higher infective doses (10^8–10^9) increase the attack rate, shorten the incubation period, and may produce severe gastrointestinal disease depending on the susceptibility of the host.[61,62] The organism is ubiquitous in the environment and illness usually results from the ingestion of contaminated food. Small numbers (i.e., <1000) of bacteria do not usually survive the defenses of the gastrointestinal tract in healthy adults. However, case reports indicate that certain serovars (e.g., *Salmonella* Typhimurium, *Salmonella* Heidelberg, *Salmonella* Napoli, *Salmonella* Eastbourne) may produce gastrointestinal illness following inoculation with infective doses below 10^3.[63,64]

CLINICAL RESPONSE

The clinical manifestations of *Salmonella* infections include the following five main syndromes: enterocolitis, enteric fever, bacteremia, localized infection, and a chronic enteric or urinary carrier state. Complications of *Salmonella* infections include bacteruria, meningitis, septic arthritis, osteomyelitis, cholangitis, and pneumonia. These latter complications usually occur in immunocompromised patients. These patients typically develop these complications without obvious gastrointestinal symptoms, particularly after exposure to the serovar, *Salmonella* Choleraesuis.[13] Most healthy adults usually experience only self-limited diarrhea for 1–2 days.

Enterocolitis

The most common form of *Salmonella* infection is enterocolitis. *Salmonella* gastroenteritis is difficult to distinguish clinically from bacterial enterocolitis caused by other bacterial pathogens. The typical incubation period is about 6–72 hours with a median onset about 18–24 hours after eating contaminated food.[42,65,66] Patients present with the acute onset of fever, diarrhea, and abdominal cramps. Diarrhea is the cardinal manifestation of *Salmonella* gastroenteritis that ranges from a few loose stools to a severe watery diarrhea. In a majority of the cases, the stools are nonbloody and moderate in volume, although gross blood and tenesmus may occur in some cases. The presence of very bloody diarrhea suggests *Shigella* or enterohemorrhagic *E. coli* infection. Nausea and vomiting are brief (i.e., few hours) or absent, but myalgias and headache occur commonly. Chills, fever (38.0°C–39.0°C/100.4°F–102.2°F), and abdominal cramps develop in most patients with *Salmonella* enterocolitis. The fever usually resolves within 3 days and the diarrhea within 2–7 days.[67,68] Prolonged fever and diarrhea more than 7 days after the onset of illness suggest a complication or another diagnosis.

Complications of *Salmonella* enterocolitis in children and adults include reactive arthritis, Reiter's syndrome (arthritis, urethritis, conjunctivitis), and rash (erythema nodosum).[69–71] Reactive arthritis is an aseptic form of articular inflammation resulting from bacterial infections localized in the gastrointestinal or urogenital tracts. The typical manifestation of reactive arthritis is inflammation in a single joint of the lower extremity. A migratory, asymmetrical polyarthropathy typically may begin within 1–3 weeks of the onset of diarrhea.[72,73] The weight-bearing joints (knees, ankles) are the most frequently affected joints. Arthralgias typically resolve within 6 months, but symptoms may persist over one year.[74,75] Extraarticular manifestations (e.g., enthesitis, tenosynovitis, bursitis, dactylitis) can occur. Viable organisms are not detectable in synovial fluid, but immunoblotting and immunofluorescence testing of synovial fluid may demonstrate *Salmonella* lipopolysaccharide antibodies.[76] A substantial majority of these patients are HLA-B27 or HLA-B7 positive.[74,77] Other causes of reactive arthritis and Reiter's syndrome in susceptible individuals include yersiniosis, *Campylobacter* enteritis, shigellosis, and chlamydial urethritis.[78]

Bacteremia

Salmonella-induced bacteremia usually occurs in young children (<2 years),[79] sickle cell disease patients, the elderly, or immunosuppressed patients (e.g., HIV). The bacteremia is usually transient, but serious complications may develop including septicemia, septic arthritis, endarteritis, and meningitis, particularly in infants <3 months of age or in immunocompromised patients.[80] Watery diarrhea may precede the development of com-

plications, such as septic arthritis up to 2 weeks. The *Salmonella* serovars Choleraesuis and Dublin demonstrate a higher predilection for producing bacteremia in humans, often without intestinal involvement.

Enteric Fever

The term enteric fever includes typhoid and paratyphoid fever with the former caused by *S. enterica* subsp. *enterica* serovar Typhi and the latter by *S. enterica* subsp. *enterica* serovars Paratyphi A, B (*Salmonella* Schottmuelleri), or C (*Salmonella* Hirschfeldii).[81] The clinical syndromes associated with these two types of infections are similar, but the paratyphoid fever is usually less severe than typhoid fever. Classically, the incubation period for the onset of enteric fever is about 7–21 days with active invasion of gut lymphoid tissue with the establishment of bacterial foci in the gut during the second and third week postexposure, respectively, to *Salmonella* Typhi and *Salmonella* Paratyphi. Symptoms of *Salmonella*-induced enteric fever include recurrent high fever, headache, meningismus, nausea, anorexia, myalgias, cough, and sore throat. Leukopenia, a relative bradycardia, and "rose spots" occur more often during typhoid fever than paratyphoid fever. The infection may be localized to the gastrointestinal tract, respiratory tract, urinary tract, or musculoskeletal system. Occasionally, overwhelming sepsis occurs. Intestinal bleeding during typhoid fever may occur in the ileum or proximal colon as a result of multiple ulcerations.[82] Other potential complications of enteric fever include coma, seizures, meningitis, intestinal perforation, septic arthritis, pneumonia, cholecystitis, hepatitis, osteomyelitis, parotitis, orchitis, and nephritis. The mortality rate of untreated patients is about 10%.

Local Infection

Soft tissue infections are relatively rare complications of exposure to *Salmonella* serovars with most cutaneous infections developing in immunocompromised patients. Case reports associated a hemorrhagic cellulitis with nontyphoid salmonellosis[83] and a cutaneous ulcer with *Salmonella* Typhi.[84]

Asymptomatic Carriage

Typically, clearance of Salmonella by asymptomatic carriers requires about one month depending on host factors, *Salmonella* serovar, and the extent of the *Salmonella* infection.[85] However, chronic or persistent carriers excrete *Salmonella* in the stool for more than one year. The incidence of chronic, asymptomatic carrier state following infection of healthy patients by nontyphoidal salmonella is relatively low (i.e., <1%).[86] Asymptomatic, infected food handlers, hospital staff, or patients may be sources of nosocomial *Salmonella* outbreaks.[87,88] Some survivors become asymptomatic carriers, and an Indian case-control study suggests that the asymptomatic carrier state increases the risk of carcinoma of the gallbladder.[89]

DIAGNOSTIC TESTING

Analytical Methods

There are approximately 40 AOAC (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) official methods of analysis for *Salmonella,* primarily for the detection of these organisms in food.[90]

Biomarkers

Salmonella are facultative anaerobes that grow well in standard blood and tissue culture media. Although there are about 2,500 antigenically distinct *Salmonella* serovars, most salmonellosis results from about 10 *Salmonella* serovars (Typhimurium, Newport, Enteritidis, Infantis, Heidelberg, Agona, St. Paul, Derby, Oranienburg, Typhi). Up to two-thirds of subjects over 5 years of age continue to shed *Salmonella* in the stool 2–3 weeks after the onset of illness. In a review of 32 studies involving over 2,800 cases of salmonellosis, the median duration of salmonella excretion was 5 weeks.[86] In patients over the age of 5 years with symptomatic infections or patients infected with serovars other than *Salmonella* Typhimurium, persistent excretion of *Salmonella* in the stool is rare (<1%). Stool cultures establish the disease state, and sensitivities help select the appropriate antibiotic. Blood and urine cultures during the active phase of enteric fever frequently are positive for *Salmonella* serovars.

Abnormalities

The leucocyte count during *Salmonella* enterocolitis is usually normal. Febrile agglutinin tests to *Salmonella* group antigens are difficult to interpret and are less specific than clinical and epidemiological findings.[91]

TREATMENT

Cases of typhoid fever should be promptly treated with appropriate antibiotics (fluoroquinolone drugs with ceftriaxone and azithromycin as alternatives). Antibiotic therapy is *not* usually indicated in uncomplicated nontyphoidal *Salmonella* enterocolitis, and antibiotics

should be administered selectively to bacteremic patients and high-risk individuals (sickle cell disease, diabetes, AIDS, cancer, immunosuppressive therapy, elderly, infants). Although treatment with quinolones may decrease the duration of symptoms of *Salmonella* enterocolitis by 1–3 days, the clinical significance of this improvement is uncertain.[94] The administration of quinolones in children or pregnant women should be done *only* after a careful evaluation of the risks and benefits of quinolone use. Consequently, most patients with mild *Salmonella* enterocolitis do not require antibiotic treatment.[92] Although quinolones do not unequivocally prolong the carrier state and there is limited evidence that antibiotics eradicate the carrier following *Salmonella* enterocolitis,[93] the use of antibiotics does not consistently shorten or eradicate the carriage of *Salmonella* organisms.[94] Antibiotics for the treatment of salmonellosis include ampicillin, trimethoprim-sulfamethoxazole, extended spectrum cephalosporins (cefotaxime, ceftriaxone), and fluoroquinolones (ciprofloxacin, ofloxacin). The choice of antibiotics depends on the susceptibilities or the presence of multidrug-resistant strains of *S. typhimurium*. Although fluoroquinolones and extended spectrum cephalosporins are alternatives for drug-resistant strains of *Salmonella*, low-level resistance is also emerging to these antibiotics.[95] Chloramphenicol resistance is a simple screening test for the 5-drug-resistant pattern (ampicillin, chloramphenicol, streptomycin, sulfonamides, tetracycline).[96] Either ampicillin or trimethoprim-sulfamethoxazole is the initial antibiotics of choice unless stool culture or local drug-resistance pattern indicate a lack of sensitivity to local organisms. Alternatives for patients with multiple allergies or unusually resistant organisms include azithromycin and aztreonam. Treatment with antibiotics probably does not induce a carrier state or alter the duration of *Salmonella* excretion in the stool.[97]

Treatment with an antimotility agent (e.g., loperamide) may decrease the number of diarrheal stools, and this treatment probably does not prolong the course or increase the incidence of the carrier state.[98,99] However, antimotility agents should be used with caution in patients with bloody diarrhea because the use of these agents are contraindicated in patients with infections resulting from Shiga toxins. Antimotility agents are not recommended in children under the age of 5 years. Because most bacterial gastrointestinal infections are self-limited, a positive stool culture does not mandate initiation of antibiotic therapy.[100] Such patients should be reevaluated and if symptoms persist or worsen, antibiotic therapy is appropriate.

Treatment of reactive arthritis involving *Salmonella* includes NSAIDs and sulfasalazine.[78] Steroids are administered when inflammatory symptoms are resistant to NSAIDs. Treatment for refractory cases includes the administration of azathioprine, methotrexate, cyclosporine, or tumor necrosis factor-alpha blockers (adalimumab, etanercept, infliximab).

Chapter 20

SHIGELLA SPECIES
(Shiga Enterotoxins)

Cyrus Rangan, MD, FAAP

HISTORY

Shigella species are gram-negative, facultatively anaerobic, nonlactose fermenting, nonmotile bacilli. Japanese physician Kiyoshi Shiga isolated *S. dysenteriae* type 1 in 1896 during an outbreak of acute bacillary dysentery in Japan.[1] American bacteriologist Simon Flexner discovered *S. flexneri* in 1899 in Manila,[2] and subsequently the Danish bacteriologist Carl Olaf Sonne discovered *S. sonnei* in 1906 in Copenhagen.[3] American microbiologist Mark Frederick Boyd discovered *S. boydii* in 1921 in India.[3] All four of these *Shigella* species are pathogenic to humans. Infections by *Shigella* species differ from most other enteropathogenic infections by the abrupt onset of clinically severe symptoms and the high rates of bacterial invasion, especially in young children. *Shigella* species are genetically similar to both enteroinvasive (EIEC) and enterohemorrhagic (EHEC) *Escherichia coli*.

EXPOSURE

Shigellosis results from infection by the following four *Shigella* species: *S. dysenteriae* (Shiga, corrig.) Castellani and Chalmers (serogroup A), *S. flexneri* Castellani and Chalmers (serogroup B), *S. boydii* Ewing (serogroup C), and *S. sonnei* (Levine) Weldin (serogroup D).[4] Most of these serogroups are subdivided into multiple serotypes based on an *O*-antigen component of the lipopolysaccharide within the outer membrane of the cell wall. The exception is serogroup D (*S. sonnei*), which contains a single serotype. An estimated 500,000 cases of *Shigella* infections occur each year in the United States with over 150,000,000 annual cases worldwide.[5] In the United States and other developed countries, *S. sonnei* is the most common serogroup. The highest risk of shigellosis occurs in residents of developing countries and travelers to these nations, primarily as a result of *S. flexneri* infections with outbreaks occurring frequently secondary to *S. dysenteriae* infections. The majority of *Shigella* cases occur in children, primarily <5 years of age.[6] Consequently, family members are also at high risk of secondary transmission.[7] However, residents of high-risk regions acquire immunity to endemic serotypes with repeated infections.[8] *S. dysenteriae* is endemic to developing nations, whereas *S. boydii* occurs primarily in India. Although *S. sonnei* is the most commonly isolated *Shigella* species in the United States, *S. flexneri* is a common isolate in immunocompromised individuals and male homosexuals.[9] Other enteric illnesses with potential sexual transmission include *Salmonella, Campylobacter, Giardia lamblia, Entamoeba histolytica*, and hepatitis A.

Source

Environment

Humans are the only natural hosts for *Shigella*, and these organisms are endemic to developing nations with substandard sanitation and hygiene that facilitate fecal-oral transmission of bacteria.[10] Rarely, asymptomatic *Shigella* carrier states result in the excretion of *Shigella* organisms

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

for up to one year after the initial infection.[11] *Shigella* outbreaks associated with drinking water typically result from the ingestion of well water contaminated with feces.[12] Shared water supplies in campgrounds, carnivals, and nonchlorinated swimming pools are also environmental sources of pathogenic *Shigella* species.[13–15] House flies may transport *Shigella* from feces to food on farms and in households.[16]

ANIMAL

Humans represent the primary animal reservoir for *Shigella* transmission. Food animals do not typically carry pathogenic *Shigella* species.[17]

FOOD

Shigella sonnei infections from undercooked meat and contaminated water are responsible for the vast majority of US cases of shigellosis.[18] Any food, milk, or drinking water source with exposure to fecal contamination may harbor *Shigella*, including cold food on commercial airlines.[19,20] Contamination of food by *Shigella* can occur as a result of the handling of food by asymptomatic carriers of *Shigella*. Following inoculation of *S. sonnei* in foods during a laboratory study, the bacterial population declined rapidly to undetectable levels within 2 days when dried on smooth surfaces of tomatoes.[21] However, populations of *S. sonnei* populations did not decrease in potato salad and ground beef stored at 2.5°C (37°F) or 8°C (46°F) over the shelf life of the products.

Food Processing

Proper cooking and refrigeration of food are the most effective means to control *Shigella.* Because *Shigella* survives in highly acidic environments; acid additives in foods do not effectively eliminate *Shigella* growth in home-prepared or commercially prepared foods.[22,23]

TOXINS

Physiochemical Properties

Shigella grows optimally at pH 4.5, but survives in a pH range of 2 to 5, permitting easy transit of these bacteria through the stomach.[24] *Shigella* reaches the large intestine by forming the following plasmid-encoded proteins: 1) ompR-envZ (protects against bile salts and high osmolarity), 2) osmZ (protects against relatively high temperature of the human body), and 3) kcpA (maintains bacterial mobility through the small intestine).[25] *Shigella* strains produce at least two enterotoxins including a chromosome encoded *Shigella* enterotoxin 1 and a large plasmid-associated *Shigella* enterotoxin 2. These two plasmid-encoded Shiga enterotoxins act similarly to kill host cells. In patients with traveler's diarrhea, shiga enterotoxin 1 occurs almost exclusively in *S. flexneri*, whereas Shiga enterotoxin 2 is a plasmid-encoded toxin found in almost all *Shigella* species.[26] Shiga enterotoxins are very similar to the Shiga-like toxins of enteroinvasive (EIEC) and enterohemorrhagic (EHEC). Shiga enterotoxins are composed of an A subunit, which is responsible for the biochemical effect of shiga toxin, surrounded by a ring of five B subunits.[27] The B chains bind the toxin to cell surface receptors, allowing the A chains to enter the interior of the cell. Inside the cell, the A chains cleave the *N*-glycosidic bond of adenine at nucleotide position 4324 in the 28S rRNA of the 60S ribosomal subunit. The phage-borne Shiga toxin is a potent protein-synthesis inhibitor, primarily in the vascular endothelium that is produced mainly by *S. dysenteriae* serotype 1. This Shiga toxin and Shiga toxin produced by certain strains of *Escherichia coli* are genetically and antigenically identical, and both strains are capable of causing hemolytic-uremic syndrome (HUS).[28]

Mechanism of Toxicity

Typically, *Shigella* infections are limited to the intestinal mucosa. *Shigella* evades intestinal host defenses to reach basolateral surfaces intact.[29] These organisms invade columnar epithelial cells of the terminal ileum and colon, where they multiply intracellularly prior to the onset of symptoms. *Shigella* enters columnar epithelial cells through the basolateral surface rather than attaching to the mucosal surface of columnar epithelial cells. Lymphofollicular M cells transcytose *Shigella* to a subepithelial macrophage, which phagocytoses the organism. *Shigella* then degrades the phagosome via plasmid-encoded siderophores, superoxide dismutase, and somatic antigens. *Shigella* species deliver a plasmid-encoded invasion plasmid antigen complex (IpaA-IpaD) via a type-III secretion system similar to EHEC.[30] The insertion of IpaB and IpaC into the host membrane forms a 25A pore that allows the passage of other infective proteins and eventually causes cell lysis. IpaB is essential for the induction of apoptosis of the macrophage, release of interleukin-1β, and deposition of *Shigella* organisms along the basolateral surfaces of adjacent columnar epithelial cells.[31] Interleukin-1β recruits neutrophils into tight junctions, disrupts their integrity, and allows the direct passage of additional *Shigella* organisms from the intestinal lumen to the basolateral sur-

faces of columnar epithelial cells. Columnar epithelial cells promptly endocytose *Shigella* at the basolateral surface.[32] Lysis of epithelial cell vacuoles allows *Shigella* to multiply in the cytosol of epithelial cells. The type-III secretion system binds to the epithelial junctional complex of the adjacent columnar epithelial cell and subsequently rearranges the cytoskeleton by inducing actin filaments to form pedestal-like polymers.[33] The rearranged cytoskeleton buckles the epithelial cell membrane. A plasmid-encoded intercellular spread protein (IcsA) mediates transport of *Shigella* through the buckled membrane and into adjacent epithelial cells, where multiplication continues.[34] Shiga enterotoxins mediate clinical symptoms via two mechanisms. First, Shiga enterotoxins bind to membrane receptors to block the absorption of water and electrolytes, occasionally leading to brief distinct prodrome of osmotic diarrhea preceding dysenteric symptoms.[35] Second, Shiga enterotoxins exert a cytotoxic effect in which the B subunit binds to membrane glycolipid GB_3 and the A subunit enters the cytosol of the columnar epithelial cell. The A domain binds to the 60s ribosomal subunit and halts protein synthesis; these actions result in cell death.[35] Another plasmid-encoded intercellular spread protein (IcsB) lyses the epithelial cell membrane.[32] Cell death results in mucosal erythema, edema, and inflammation, leading to ulceration, microabscess, necrosis, hemorrhage, and purulent mucoid exudates with fecal leukocytes.[36] Histopathology of these lesions resembles those of ulcerative colitis.[37] Repeated infections in young children may result in scarring and chronic malabsorption.[38] Systemic dissemination of *Shigella* and Shiga enterotoxin results in systemic effects outside the gastrointestinal tract.[39–41] Binding of Shiga enterotoxin to renal endothelial cells may result in hemolytic-uremic syndrome in children.[42]

DOSE RESPONSE

The dose of *Shigella* organisms necessary to produce an infection depends on the virulence of the strain and the susceptibility of the host. The attack rate for 152 volunteers inoculated with one of four strains of *Shigella* ranged from about 25 to 50%.[43] In this case series, as few as 10 *Shigella* dysenteriae 1 organisms caused shigellosis in the human volunteers.

CLINICAL RESPONSE

The incubation period for *Shigella* bacteria is about 1–2 days. A brief nonspecific prodrome of osmotic, watery diarrhea may precede dysentery; in mild cases the watery diarrhea does not progress to dysentery.[44] Additional initial symptoms of shigellosis include anorexia, malaise, and weakness. Anorexia may persist into the convalescent period. Sudden onset of severe cramping, tenesmus, fever, myalgias, and frequent, small bloody, mucoid stools characterize bacillary dysentery.[45] Vomiting is rare, and large fluid volume losses with significant dehydration are not typical in most cases of shigellosis.[46] Seizures may occur during Shigella infections, particularly in children, and in this group of patients the presence of seizures does not necessarily indicate the presence of intracranial infection.[47] *S. dysenteriae* usually produces more severe disease, and patients with severe infections may pass >20 dysenteric stools in one day. Children may lose significant protein and immunoglobulins in their stools, leading to malnutrition, severe electrolyte disturbances, and increased susceptibility to further infections.[38] Intestinal perforation, rectal prolapse, or toxic megacolon may complicate ulcerations in the colonic mucosa.[48] Rare complications of disseminated *Shigella* include meningitis, osteomyelitis, and bacteremia as well as hemolytic-uremic syndrome in children and thrombotic thrombocytopenic purpura in adults.[41,49] *Shigella* septicemia occurs rarely in healthy individuals, but may occur more often in immunocompromised patients.[50,51] Complications of *S. flexneri* infections include postinfectious inflammatory arthritis or Reiter's syndrome, which is usually associated with human lymphocyte antigen B27 (HLA-B27).[52] Immunity to *Shigella* is serotype-specific. The differential diagnosis of patient with suspected shigellosis (i.e., bloody, mucoid stools) includes infections by enteroinvasive *E. coli*, *Campylobacter* species, *Salmonella enteritidis*, *Yersinia enterocolitica*, and *Entamoeba histolytica*.

DIAGNOSTIC TESTING

Analytical Methods

Shigella remain viable outside the human body for a limited time; therefore, stools samples should be processed for *Shigella* within a few hours of collection. Use of transport media (e.g., Cary-Blair, buffered glycerol saline) improves the yield of stool samples for *Shigella*. The typical culture media for *Shigella* is *Salmonella-Shigella* (SS) agar, but these organisms will also grow on MacConkey agar and other enteric media (e.g., Hektoen enteric, xylose lysine desoxycholate, desoxycholate citrate agar). Stool specimens may be pre-enriched in selenite gram-negative broth to improve the yield from culturing.[53] After incubation, surviving colonies are streaked onto triple sugar iron agar to isolate *Shigella* species. A characteristic feature of *Shigella* colonies is the production of acid, but not hydrogen sulfide, on triple sugar iron agar.[54] Polymerase chain reaction

(PCR) demonstrates superior sensitivity over stool culture (i.e., 96% vs. 54%).[55]

Biomarkers

Leukocytosis or leukopenia may be present; however, relative leukopenia with significant left shift should prompt the clinician to suspect shigellosis.[56] Standard blood cultures may be positive in rare cases of Shigella sepsis. Antibody titers are not useful for the diagnosis of shigellosis.

Abnormalities

Stool samples in shigellosis reveal blood, mucous, and sheets of fecal leukocytes.[57] Colonoscopy reveals multiple ulcerations with severe inflammation and erythema, similar to patients with ulcerative colitis.[36] Fluid and electrolyte loss can cause hypernatremia (serum Na > 150 mEq/L), hyponatremia (serum Na < 130 mEq/L), hypokalemia (serum K < 3.0 mEq/L), hypochloremia, elevated urine specific gravity (SpG > 1.020), and hyperphosphatemia. Low serum bicarbonate concentrations result from lactic acid production, whereas elevation of serum bicarbonate concentrations occur secondary to contraction alkalosis. Hypoglycemia may also occur, particularly in children. The presence of high numbers (i.e., >30%) of bands in the complete blood count in an adult with diarrhea is highly suggestive of shigellosis.[58] However, the band count in patients with shigellosis is not sensitive in children. ST-T flattening and arrhythmias may be observed on electrocardiogram.

TREATMENT

Shigellosis is usually a self-limited disease that responds to hydration. Treatment includes bowel rest and rehydration with fluid and electrolytes replacement. Oral replacement may be sufficient, but affected patients may experience significant anorexia, necessitating intravenous fluid replacement and hospitalization in cases of significant dehydration or severe electrolyte abnormalities, particularly in young children or elderly patients.[59,60] The clinical symptoms of shigellosis usually resolve spontaneously within 7 days; however, all cases of confirmed or suspected shigellosis should be treated with antimicrobials to avoid complications, sequelae, disease recurrence, and secondary transmission.[41] Antimicrobial therapy decreases illness duration from 7 days to 48–72 hours, significantly decreases bacterial shedding, and reduces the incidence of extraintestinal manifestations.[41] Intravenous or intramuscular ceftriaxone or cefixime are administered for 5 days in children.[61] Adults with shigellosis respond to ceftriaxone, azithromycin, or quinolones in susceptible strains; however, resistance to quinolones is prevalent.[62,63] Cefixime is not effective for the treatment of shigellosis in adults.[64] *Shigella* species commonly are resistant to sulfonamides, penicillins, and tetracyclines worldwide.[65,66] Many medical sources do not recommend opiates, loperamide, and other antimotility agents during shigellosis because of the concern about the potential for bacterial invasion following the use of the medications.[67,68] However, there are inadequate clinical data to determine the efficacy and complications associated with the use of these agents in shigellosis. In a study of 44 patients with shigellosis treated with ciprofloxacin 500 mg twice daily for 3 days, the use of loperamide decreased the number of diarrheal stools and shortened the duration of illness when compared with placebo. No prolonged fever or extended excretion of *Shigella* was noted in this study, but the sample size was relatively small. In endemic regions, maternal antibodies from breast milk protect young infants from Shigella infections.[69]

Chapter 21

STAPHYLOCOCCUS AUREUS

CYRUS RANGAN, MD, FAAP

HISTORY

Staphylococcus aureus subsp. *aureus* Rosenbach (*S. aureus*) is a facultative anaerobic, nonspore-forming, gram-positive coccus that is one of the two most common causes of foodborne illness along with *Salmonella* serovars.[1] Although the bacterium was first isolated from furuncles by Louis Pasteur in 1878 and further classified by Rosenbach in 1884, *S. aureus* was not identified as a cause of foodborne toxicity until 1914.[2,3] In 1930, Dack et al demonstrated that a *Staphylococcus*-contaminated sponge cake with cream filling was the source of an outbreak of food poisoning.[4] Staphylococcal enterotoxins (SEs) were isolated after analyses of *S. aureus* strains in foodborne illness outbreaks by M.S. Bergdoll at the University of Wisconsin-Madison.[5] SEs comprise one group of toxins elaborated by *S. aureus*. Nonenterotoxigenic staphylococcal toxins include toxic shock syndrome toxin (TSST-1) and exfoliatins A and B with the latter being associated with scalded skin syndrome. A famous series of four US outbreaks of *S. aureus* food poisoning was traced to improperly canned mushrooms imported from China, prompting US trade restrictions on the import of Chinese mushrooms.[6] In 1992, a large outbreak of *S. aureus* food poisoning occurred in a Texas school system when 25% of nearly 6,000 children in 16 different schools developed vomiting after eating prepared lunches that were transported by trucks from a common source. Chicken salad was the food source for this outbreak. The chicken was boiled the day before and cooled slowly, while the salad ingredients were mixed the following day. After transport, the food was held at room temperature for at least an hour at the various schools. Enterotoxigenic *S. aureus* was subsequently identified in the chicken salad.[7] In another outbreak, over 50% of 8,000 individuals at a gathering in Brazil experienced acute gastroenteritis in 1998. Sixteen patients died from irreversible multisystem failure. Enterotoxigenic *S. aureus* was identified in food served at the gathering.[8] Although several staphylococcal species (*S. cohnii, S. epidermidis, S. haemolyticus, S. intermedius, S. xylosus*) other than *S. aureus* produce SEs, coagulase positive *S. intermedius* is the only other non-*S. aureus* species clearly associated with staphylococcal food poisoning.[9,10]

EXPOSURE

Source

ENVIRONMENT

Staphylococcus aureus is a ubiquitous pathogen found in air, dust, and sewage.[11] Populations of bacteria in these milieus generally originate from human and animals. Surfaces of equipment used in food gathering and harvesting may harbor *S. aureus* in fomites for several days.[12]

ANIMAL

Up to 50% of mammals carry *S. aureus* asymptomatically in the nares and throat, on skin, and in hair.[13] Mastitis in dairy cows is highly correlated to the appearance of *S. aureus* in milk.[14] Animals are the primary source of *S. aureus* contamination of raw foods, whereas

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

food handlers are the primary source of contaminated prepared foods.[15]

Food

Staphylococcus aureus may be present in virtually any food because it can reproduce within wide ranges of temperature, acidity, and salt content.[16] Up to 50% of *S. aureus* isolates from various foods are enterotoxigenic strains, but enterotoxins are not usually produced until populations reach 10^6 CFU/gm.[17] The main sources of staphylococcal contamination are food handlers (i.e., asymptomatic carriers or persons with open lesions), and contamination typically occurs after heat treatment of the food.[18,19] However, some food sources (e.g., raw meat, cheese, sausage) of staphylococcal food poisoning result from animal contamination. Commonly identified sources of *S. aureus* foodborne illness include red meats and sausages; poultry; cheeses; cream-filled pastries; milk; dairy products; and salads made with chicken, mayonnaise, pasta with tomato sauce, egg, tuna, and macaroni.[20,21] Fermented dairy products (e.g., soft cheeses, creams) are well-recognized potential sources of *S. aureus* because of the prolific growth of these bacteria at temperatures required to make these foods.[22] Dressed animal carcasses are commonly contaminated with staphylococci.

Food Processing

Inadequate refrigeration and heating are the most common reasons for the proliferation of *S. aureus* in food. Refrigeration temperatures <45 °F (7 °C) are adequate to keep growth to a minimum, and bacteria are readily destroyed by routine cooking temperatures exceeding 140 °F (60 °C).[23] Existing commercial sanitization techniques are adequate to control growth of *S. aureus*. Therefore, growth of *S. aureus* during commercial food processing usually results from poor sanitary practices.[24] Because *S. aureus* does not form spores, regeneration of colonies does not occur during cooling and reheating of properly cooked food. However, food is easily recontaminated with *S. aureus* from improper preparation and processing, particularly from human carriers. Thus, foods at high risk for *S. aureus* contamination primarily involve food, which require frequent handling after initial cooking or baking (e.g., cream-filled pastries).[25] Kitchen utensils (e.g., knives, meat grinders and slicers, cutting boards) also harbor *S. aureus* in fomites.[26] SEs are destroyed by heat sterilization and canning, though they may escape destruction if present in high enough concentrations. Pasteurization kills *S. aureus*, but this process may not completely destroy preformed SEs.[27] Acid treatments in food processing (pH < 2) can also deactivate SEs, but many SEs regain their activity as soon as pH becomes more alkaline.[28] Because *S. aureus* is a facultative anaerobe, anaerobic processing conditions are not effective in inhibiting *S. aureus* growth in food.[29]

TOXINS

Physiochemical Properties

Staphylococcus aureus grows optimally at 86 °F–98 °F (30 °C–37 °C), but these bacteria may grow at temperatures from 45 °F–120 °F (7 °C–49 °C).[30] The pH range for staphylococcal proliferation is 4.5 to 9.3 with optimal growth between 7.0 and 7.5. Most strains of *S. aureus* are highly tolerant to sugars and salts, and these strains can grow over a water activity (a_w) range of 0.83 to >0.99. *S. aureus* exerts its effects by the production of staphylococcal enterotoxins. SEs are single polypeptides of 25–28 kDa that are highly heat resistant and remain active even when the staphylococci are destroyed. SE production is usually inhibited at pH < 5. Most SEs are resistant to proteolytic enzymes (e.g., pepsin, trypsin); consequently, these toxins remain intact during transit through the gastrointestinal tract.[31] Production of SEs is tightly governed by an accessory gene regulator (*agr*) system, which is dormant during the exponential growth phase of *S. aureus*. An autoinducible quorum-sensing system triggers the expression of *agr* when *S. aureus* food counts reach 10^6 CFU/gm.[32] SEs are heat-stable, but the high temperatures used in commercial food processing can inactivated these toxins. Fourteen different SEs have been identified: SEA, SEB, SEC1 and related isotypes (SEC2, SEC3), SED, SEE, SEG, SEH, SEI, SEJ, SEK, SEL, SEM, SEN, and SEO. In a study of commercial Italian foods containing SEs, the most common enterotoxins were SEA and SEC.[33] SEB (CAS RN: 11100-45-1) is a heat-stable enterotoxin, which is a potential terrorist weapon when released as an aerosol (SEB respiratory syndrome).[34] SEG, SEH, and SEI are relatively minor enterotoxins.[35] Frequently, food implicated in staphylococcal food poisoning contains more than one enterotoxin. Enterotoxin F was the original name given to the toxin that is now known as TSST-1. Although the SEs are antigenically distinct, they have a high degree of homology; 26–83% of their amino acid sequences are similar. The majority of SEs contains a distinctive cystine loop that may influence the severity of vomiting.[36]

Mechanism of Toxicity

Most SEs produce vomiting through stimulation of gastrointestinal motility via direct interaction of SEs with

gut epithelial emetic receptors. SEs cause hyperemic, inflammatory reactions on the mucosal surfaces of the stomach, duodenum, and jejunum via generation of inflammatory mediators such as prostaglandin E2, leukotriene B4, and 5-hydroxyeicosatetraenoic acid. Neutrophils and macrophages subsequently infiltrate these lesions, but these cells do not penetrate the lamina propria. Mucopurulent fluid is then discharged into the duodenum while brush border integrity is disrupted in the jejunum.[37] SEA, SEB, SEC1, SED, SEE, and SEH are characterized as "superantigens," which induce symptoms via stimulating mitogenic activity and cytokine production. These superantigens activate the immune system, resulting in T cell proliferation by interaction with Class II MHC molecules on macrophages and specific V beta chains of the T cell receptor. The important feature of this interaction is the subsequent generation of interleukin-1 (IL-1), interleukin-2 (IL-2), tumor necrosis factor (TNF), and other lymphokines.[38] Although the mechanism of action is unknown, IL-2 likely plays a significant role in the pathogenesis of gastrointestinal symptoms. Evidence for the IL-2 mechanism is deduced from cancer patients, who experience significant vomiting when treated with IL-2 immunomodulation chemotherapy.[39] SEs occasionally cross mucosal surfaces when massive doses of SE are present, potentially leading to a clinical syndrome similar to toxic shock.[40]

DOSE RESPONSE

The minimum dose of SE required to induce symptoms depends on the potency of the particular SEs elaborated in food and individual sensitivities, and the dose ranges from 1 ng to 1.0 μg of total enterotoxins. Typically, 100–200 ng of staphylococcal enterotoxin in sensitive subjects causes symptoms of staphylococcal intoxication.[41,42] Sufficient SE production generally occurs when populations of enterotoxigenic *S. aureus* exceed 10^6 CFU/gm.[32] The refrigeration (<10 °C/50 °F) or the heating (>45 °C/113 °F) of food prevents the proliferation of staphylococcal organisms to the numbers necessary to form detectable concentrations of enterotoxins.

CLINICAL RESPONSE

The clinical response to SEs resembles the emetic syndrome induced by *Bacillus cereus. S. aureus* food poisoning is characterized by nausea, vomiting, retching, and abdominal cramping with diarrhea on rare occasions. Symptoms may arise as early as 30 minutes after exposure, but symptoms may be delayed up to 8 hours after exposure. In a large outbreak of staphylococcal food poisoning resulting from the ingestion of contaminated powdered milk, about 83% of the patients developed illness within 6 hours with a peak onset of 3–4 hours.[43] By 12 hours after ingestion, approximately 96% of these patients developed symptoms of food poisoning. Diarrhea virtually never occurs without vomiting; therefore, the occurrence of diarrhea without vomiting should prompt the clinician to seek other etiologies.[44] Associated symptoms of staphylococcal food poisoning include headache, dizziness, tachycardia, and other physical signs of dehydration.[45] The clinical response to SEs is self-limited, and resolves spontaneously in 24–48 hours in the majority of cases. Anorexia can persist for several days. Rare cases of systemic toxicity occur following massive SE doses with a clinical course similar to toxic shock syndrome manifested by fever, hypotension, and multiorgan failure. Death from systemic invasion of enterotoxins is extremely rare (i.e., typically < 0.03–0.4%).[46]

DIAGNOSTIC TESTING

Analytical Methods

Direct microscopic evaluation of food contaminated with *S. aureus* reveals spherical cocci in pairs, chains, or grape-like clusters (*staphyle* [Greek]: bunches of grapes). Direct plate count determines the size of the population. Surveillance of high-risk food products for *S. aureus* is also performed using direct plate counts.[47] There are at least 8 AOAC (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) microbiological methods available for the detection and enumeration of *S. aureus* in various food matrixes.[48]

1. AOAC official method 966.23 determines the aerobic plate count, most probable number of coliform bacteria, and the number of *S. aureus* in food products.
2. AOAC official method 995.12 is a latex agglutination method for the identification of *S. aureus* isolates from foods.
3. AOAC official method 975.55 is a surface plating method for the isolation and enumeration of *S. aureus* in foods expected to contain ≥10 cells/g of food.
4. AOAC official method 987.09 is used for the detection and enumeration of small numbers of *S. aureus* in food ingredients and food expected to contain large populations of competing species.
5. AOAC official method 2001.05 is applicable to the rapid enumeration of confirmed *S. aureus* organisms in pasta filled with beef and cheese, frozen

hash browns, cooked chicken patty, egg custard, frozen ground raw pork, and instant nonfat dried milk.
6. AOAC official method 2003.11 is applicable to the enumeration of *S. aureus* in cooked and diced chicken, ham, salmon, and pepperoni.
7. AOAC official method 2003.08 is applicable to the enumeration of *S. aureus* in ice cream, raw milk, yogurt, whey powder, and cheese.
8. AOAC official method 2003.07 is used for the enumeration of *S. aureus* in frozen lasagna, custard, frozen mixed vegetables, frozen hash browns, and frozen batter-coated mushrooms.

The presence of large numbers of staphylococci in foods is not sufficient to incriminate a specific food as a source of staphylococcal food poisoning because not all staphylococcal strains are enterotoxigenic. Serologic testing can determine the enterotoxigenicity of specific isolates. In foodborne illness outbreaks, enterotoxins are separated from food by selective adsorption on ion exchange resins. Enterotoxins are then identified in food by tracer-labeled immunoassay. Enzyme-linked immunosorbent assay (ELISA), reverse passive latex agglutination, and radioimmunoassay (RIA) are the most commonly utilized methods for identification of enterotoxins.[49] These highly sensitive methods are able to detect enterotoxin concentrations as low as 1.0 ng/gm of food. AOAC official method 993.06 is a polyvalent enzyme immunoassay method for the detection of 1.3–3.3 ng/mL of staphylococcal enterotoxin in extracts prepared from selected foods containing 4–10 ng/mL of staphylococcal enterotoxin. Specific toxin serotypes A to E are not differentiated. Although commercial assays detect the more common staphylococcal enterotoxins (SEA–SEE), these assays do not necessarily detect less common staphylococcal enterotoxins (SEG–SEO).[50] Multiplex PCR with rapid DNA isolation quickly and comprehensively identifies the genes for SEs, TSST, and exfoliatins in *S. aureus* isolates from human specimens, but this method is not widely available.[24] Detection of enterotoxigenic strains of *S. aureus* $>10^6$ CFU/gm of food and enterotoxin >1.0 μg/gm of food with adequate clinical correlation is sufficient to confirm the diagnosis of staphylococcal food poisoning.

Biomarkers

Standards for measurement of SEs concentrations in emesis or other body fluids are not established. Emesis, blood, urine, and stool are not routinely tested for SEs.

Abnormalities

Staphylococcus aureus food poisoning can produce severe serum electrolyte abnormalities, with a laboratory profile similar to dehydration from gastrointestinal fluid losses. Severe dehydration involves hypernatremia (serum Na > 150 mEq/L) or hyponatremia (serum Na < 130 mEq/L), hypokalemia (serum K < 3.0 mEq/L), hypochloremia, and elevated urine specific gravity (SpG > 1.020). Low serum bicarbonate results from lactic acid production or elevated bicarbonate secondary to contraction alkalosis. The short duration of illness induced by *S. aureus* limits the severity of fluid and electrolyte imbalances, which usually resolve spontaneously.[51]

TREATMENT

Treatment includes bowel rest and rehydration with spontaneous resolution of symptoms typically occurring in 24–48 hours. Oral rehydration is usually sufficient, but intravenous fluid replacement and hospitalization may be necessary in cases of severe dehydration or severe electrolyte abnormalities, particularly in young children or elderly patients.[52,53] There are no clinical trials that demonstrate an improvement in clinical outcome, avoidance of hospitalization, or shortened duration of symptoms following the use of antiemetic agents. The short duration of symptoms generally limits the need for these medications; however, some patients may experience symptomatic relief with these agents when symptoms are severe. Antibiotics are not recommended because the illness results from the ingestion of preformed toxins rather than from the *in vivo* release of toxins or true invasion of the gastrointestinal tract. Furthermore, the injudicious use of antibiotics potentially could contribute to the increased incidence of antimicrobial-resistant *S. aureus* as a result of the rapid appearance of resistant strains after the initiation of antibiotic therapy.

Chapter 22

STREPTOCOCCUS SPECIES

Cyrus Rangan, MD, FAAP

HISTORY

Streptococci are gram-positive, facultatively anaerobic, nonmotile, nonspore forming, catalase-negative cocci, which were first discovered by Louis Pasteur in 1880. Although there are over 15 species of pathogenic streptococci, the Lancefield classification of *Streptococcus* defines the antigenic distinctions among bacteria.[1] Lancefield group A (*S. pyogenes* Rosenbach) is responsible for most foodborne streptococcal disease, whereas group C (*S. equi*), group D (*S. faecalis, S. bovis*), and group G (*S. intermedius, S. anginosus*) cause rare foodborne outbreaks.[2–4] Dairy products were the main source of foodborne streptococcal outbreaks before commercial pasteurization. Today, food handlers are the primary vectors of direct streptococcal contamination of prepared foods. Foodborne streptococcal infections typically involve the pharynx, and only rarely do these infections cause gastroenteritis. The first recorded US epidemic of foodborne pharyngitis occurred in 1968 at a US Air Force Academy, where 1,200 cadets were infected with Group A *Streptococcus* from tuna salad containing mayonnaise and hard-boiled eggs.[5] The salad was prepared by an asymptomatic food handler with a positive throat culture for the identical strain of Group A *Streptococcus* identified in throat swabs from these patients.

EXPOSURE

Source

Environment

Group A *Streptococcus* are distributed worldwide, and are more prevalent in the warmer months of spring and summer.[6]

Animal

Dairy animals harbor group A and group C *streptococci*; however, commercial pasteurization has eliminated virtually all streptococcal contamination of dairy products.[7] Humans are the primary reservoir for modern streptococcal food contamination. The pharynx and skin lesions are commonly identified sources of streptococci in traceable outbreaks.[8,9]

Food

The typical sources of foodborne streptococcal pharyngitis are inadequately handled, cold salads contaminated by food handlers with *Streptococcus pyogenes*.[10] Eggs, egg salads, tuna, mayonnaise, and cheeses are the most common sources of foodborne illness associated with

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Streptococcus pyrogenes. The risk of group A *Streptococcus* infection dramatically increases in foods prepared the day before serving or food remaining at room temperature for several hours in salad bars, buffets, or picnics.[11] With the advent of pasteurization, milk is a rare cause of epidemic streptococcal pharyngitis.[12]

Food Processing

The most effective means to control group A streptococcal food contamination include the following: proper cooking and refrigeration, purification of water, pasteurization of dairy products, sanitation of food preparation surfaces with at least 1% bleach solution, and cooking foods to 120 °C–170 °C (248 °F–338 °F).[13] Food handlers or salad bar patrons carrying streptococci in the nasopharynx or on skin lesions may directly inoculate food before or after preparation via sneezing, coughing, or handling the food with contaminated utensils or hands.[8] Protective measures include strict hygiene and surveillance of food handlers; use of protective gloves and masks; and particular care in handling cold salads, especially those containing egg products.[14]

TOXINS

Physiochemical Properties

The genus *Streptococcus* contains over 15 species. Lancefield Group A class (*S. pyogenes*) is most important as a cause of foodborne illness. Group A *Streptococcus* possesses a hyaluronic acid containing an outer capsule that encases fimbrial M proteins, which are coiled dimers of alpha-helices on the bacterial surface.[15] M proteins are serotyped 1–61. Strains with M proteins 1, 3, 5, 6, 14, 18, 19, 24, and 29 are generally associated with throat infections and rheumatic fever, whereas M proteins 2, 49, 57, 59, 60, and 61 are usually associated with skin infections.[16,17] M proteins mediate most of the group A *Streptococcus* pathogenicity along with numerous virulence determinants, including lipoteichoic acid (LTA), protein F, fibronectin-binding proteins, serum opacity factor, glyceraldehyde-3-phosphate dehydrogenase, vitronectin-binding protein, galactose-binding protein, and collagen-binding protein.[18]

Mechanism of Toxicity

Lipoteichoic acid (LTA) on the outer bacterial membrane binds loosely with fatty acids residues on fibronectin and epithelial cells on the buccal and pharyngeal mucosae.[19] The hyaluronic acid capsule binds to CD44 on epithelial cells and preserves bacterial virulence determinants.[20] M proteins 1, 3, 5, 6, 14, 18, 19, and 24 anchor the organism to throat epithelial cells, promote colonization, and induce a local inflammatory response by stimulating the production of interleukin-6 (IL-6).[21,22] M proteins 2, 49, 57, 59, 60, and 61 adhere strongly to keratinocytes, promoting colonization and infection in skin lesions.[23] Protein F adheres to fibronectin and initiates invasion into epithelial cells.[24] M protein, protein F, fibronectin-binding proteins, and serum opacity factor interact with α5 and β1 integrins on epithelial cell surfaces and promote bacterial invasion. This internalization may account for treatment failures, asymptomatic carriage, and invasion of deeper tissues (i.e., tonsillopharyngitis) in human hosts.[25,26] Once adhesion occurs, the bacterium evades host defenses by attacking the complement system, and M proteins and the hyaluronic acid capsule inhibit activation of the complement system by binding regulatory factor H.[27] Streptococcal C5a peptidase blocks chemotaxis of polymorphonuclear cells by cleaving complement factor C5a;[28] and the binding of M proteins to fibrinogen shields the bacterium from opsonization by complement factor C3b, thus inhibiting phagocytosis.[29] Leukocidins, streptolysin S, and streptolysin O form pores in leukocyte cell membranes with subsequent cell lysis.[30] Streptococcal proteinase mediates tissue damage by activating interleukin-1ß (IL-1ß), degrading vitronectin and fibronectin, and activating endothelial metalloproteases. This cascade destroys the extracellular tissue matrix and promotes an acute inflammatory response.[31–33]

Bacterial superantigens are highly potent immunostimulatory molecules produced by *Streptococcus pyrogenes* as well as *Staphylococcus aureus*. These toxins interact with MHC class II molecules and CD4+ T cells to form trimolecular complex that cause intense T-cell proliferation. The subsequent production of cytokine results in epithelial damage, capillary leak, and hypotension. The streptococcal superantigens include the classical pyrogenic exotoxins A and C along with more recently identified toxins (G–J, SMEZ, SSA).[34]

DOSE RESPONSE

The inoculum of group A *Streptococcus* required to produce pharyngitis from foodborne infections is unknown. Colony counts of group A *Streptococcus* in implicated foods range from 10^5 to 10^7 CFU/gm; however, the minimum inoculum size may be much lower.[35] The estimated size of inoculum to cause streptococcal endocarditis based on rabbit models is 3.7×10^5 to 8.5×10^6 CFU/g.[36] Patients under the age of 5 years do not typically acquire streptococcal pharyngitis because they lack epithelial cell receptors for group A *Streptococcus* adhesins.[37]

CLINICAL RESPONSE

Foodborne group A *Streptococcus* incubates for 1–3 days before symptoms develop. A brief prodrome of muscle aches, nausea, and fatigue may precede throat symptoms.[38] In comparison to airborne streptococcal pharyngitis, the onset following foodborne streptococcal pharyngitis is more abrupt, the attack rate is higher (i.e., 51–90%), and complication rates are lower.[39,40] Additionally, symptoms in foodborne disease are confined primarily to sore throat, odynophagia, fever, pharyngeal erythema, tonsillar enlargement, and submandibular lymphadenopathy, whereas cough and other respiratory symptoms usually accompany sore throat secondary to airborne streptococcal disease. Although some cases of foodborne disease may begin with respiratory symptoms, the presence of these symptoms in an outbreak suggests secondary infection. Complications such as peritonsillar abscess may represent treatment failure.[41] Foodborne infections are not usually associated with sequelae such as acute glomerular nephritis, rheumatic fever, reactive arthritis, toxic shock syndrome, pediatric autoimmune neuropsychiatric disorders associated with streptococcus (PANDAS), or septicemia in healthy individuals. Isolated cases of toxic shock syndrome or other invasive, superantigen-mediated diseases may occur in patients with underlying chronic diseases.[42] Foodborne streptococcal gastroenteritis is relatively rare, and pharyngitis is the typical presentation of foodborne streptococcal disease.[43] The development of mild, self-limited nausea, vomiting, or diarrhea in patients with foodborne streptococcal pharyngitis is relatively uncommon compared with upper respiratory tract symptoms.[44,45]

DIAGNOSTIC TESTING

Analytical Methods

Throat culture is the most common method to confirm streptococcal pharyngitis. Rapid antigen screens are 95% specific, but only 70–90% sensitive. Negative antigen screens should be followed by routine culture in suspected cases.[46] Group A *Streptococcus* produces a zone of β-hemolysis on 5% sheep blood agar in the presence of trimethoprim-sulfamethoxazole, which inhibits the growth of normal flora. Anaerobic conditions enhance streptolysin O activity.[47] DNA-based methods allow the amplification of specific genetic signals from a few cells; therefore, these analytical methods are much more sensitive and specific than the use of selective microbiological media. Polymerase chain reaction (PCR) is the basis of many nucleic acid-based detection systems. This method detects both live and dead strains of *Streptococcus*, and PCR for this bacterium yields 99% specificity and 100% sensitivity.[48] Subtyping procedures are useful for tracking individual strains responsible for outbreaks of *Streptococcus*. Analytical methods for subtyping include phenotypic subtyping (biogrouping, serotyping, phage typing, esterase typing) and genotypic subtyping (pulsed-field gel electrophoresis, multilocus enzyme electrophoresis, ribotyping, PCR-based subtyping techniques, amplified fragment length polymorphism, PCR-restriction fragment length polymorphism, repetitive element PCR, DNA sequencing-based subtyping techniques such as multilocus sequence typing). These subtyping techniques are reserved for the investigation of epidemics. Rapid DNA hybridization is an alternative technique of correlating T-antigen agglutination factors and M protein factors in human specimens to those in food specimens.[49] Throat or skin lesion specimens obtained from asymptomatic human carriers (e.g., food handlers) are tested by similar methodologies to identify potential sources of an outbreak.[50]

Biomarkers

Antistreptolysin-O and anti-DNase B titers may remain elevated in postepidemic surveillance for several months.[30]

Abnormalities

Leukocytosis with or without left shift may be observed; however, leukocyte counts are generally unnecessary for diagnosis in uncomplicated cases.

TREATMENT

If present, mild gastrointestinal symptoms typically are self-limited. Treatment of group A streptococcal gastroenteritis includes bowel rest and rehydration with fluid and electrolytes replacement. Oral replacement is usually sufficient.[51,52] Group A streptococcal pharyngitis is uniformly treated with penicillins. Despite exquisite susceptibility to penicillins, treatment failure may result from poor antibiotic compliance, reinfection, penicillin tolerance, endothelial internalization of bacteria, or the coexistence of oropharyngeal beta-lactamase-producing bacteria that degrade penicillins during therapy.[41,53] Patients with penicillin allergies may be treated with erythromycin or azithromycin; however, up to 20% of patients treated with erythromycin have positive throat cultures posttherapy.[54] Patients under the age of 5 years should not be treated presumptively with antimicrobial agents.[37] Prophylaxis of close contacts with penicillin is not more effective at preventing secondary transmission

than prompt treatment of affected victims, and prophylactic treatment may lead to unexpected penicillin allergies.[55]

Chapter 23

VIBRIO SPECIES

CYRUS RANGAN, MD, FAAP

HISTORY

Vibrio species (*Vibrios*) are gram-negative, facultatively anaerobic, oxidase-positive, motile, flagellated, curved rods.[1] During the Asiatic cholera epidemic of 1846–1863, Italian microbiologist Filippo Pacini identified *Vibrio cholerae* Pacini (*V. cholerae*) in 1854, after British physician John Snow described the epidemiologic basis for cholera transmission in 1849.[2] Robert Koch rediscovered the organism in 1884 after the Egyptian cholera outbreak of 1883.[3] *Vibrios* are ubiquitous in surface waters worldwide, and these organisms have caused recognized pandemics at least since 1817. Typically, these pandemics appeared in 7-year cycles, primarily affecting Asia and Africa. The last US epidemic occurred in 1911.[4] The classical biotype of *V. cholerae* O1 caused the sixth pandemic in Asia in 1950. Proliferation of *V. cholerae* O1 biotype El Tor initiated the seventh pandemic, which began in Asia during 1961 and spread to West Africa and southern Europe.[5] In 1991, the seventh pandemic spread to Peru, with sporadic cases occurring in the United States along the gulf coasts of Texas, Louisiana, Alabama, Mississippi, and Florida.[6] In 1993, *V. cholerae* serogroup O139 caused the eighth cholera pandemic in Bangladesh and India.[7] Subsequently, *V. cholerae* O1 El Tor emerged in the same area 3 years later.[8] *V. cholerae* is the most prevalent *Vibrio* species worldwide, whereas *Vibrio parahaemolyticus* (Fujino et al) Baumann et al is the most common *Vibrio* species responsible for gastrointestinal infections in the United States, Taiwan, and Japan. This illness is transmitted primarily by oysters and other shellfish, which regularly harbor *V. parahaemolyticus* and cause an estimated 8,000 annual cases with 60 deaths.[9] Other noncholera *Vibrio* species that cause rare cases of gastrointestinal illnesses include *V. alginolyticus* (Miyamoto et al) Sakazaki, *V. fluvialis* Lee et al., *V. furnissii* Brenner et al, *V hollisae* Hickman et al., *V. mimicus* Davis et al, and *V. vulnificus* (Reichelt et al.) Farmer.[10]

EXPOSURE

Source

ENVIRONMENT

Vibrios thrive globally in all salty surface waters, especially along coastlines and estuaries. The lifespan of these organisms in the water column is about 3 weeks. However, *Vibrios* are infrequently isolated from coastal waters between epidemics because *Vibrios* enter into a dormant, viable but nonculturable (VNC) state as water temperatures fall.[11] During warming trends, VNC *Vibrios* associate with plankton (copepods) that proliferate extensively during cholera epidemics. This phenomenon suggests that cholera epidemics are associated with both exposure to contaminated waters and global weather changes that support the growth of plankton.[12] *Vibrio vulnificus* adheres to a wide range of surfaces, including the exoskeleton of mollusks and human tissue.[13]

ANIMAL

Shellfish and plankton in warm marine and estuarine waters are the most prominent reservoirs of *Vibrio*

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

species, whereas contaminated drinking water is the primary source of transmission to humans.[14] Humans act as short-term reservoirs for 3–4 weeks in endemic areas, but person-to-person transmission is unusual because of the high inoculum required to cause disease.[15]

Food

Drinking water is the primary source of transmission of *V. cholerae*. *Vibrio* species are common contaminants of shellfish. Improperly cooked oysters, crab, lobster, mussels, and clams are the most common foodborne sources of *V. cholerae*,[16] *V. parahaemolyticus*,[17,18] and *V. vulnificus*,[19] especially shellfish harvested from fecally contaminated coastal waters. In a study of 682 batches of cooked crustaceans and molluscan shellfish from retail stores and production facilities in the United Kingdom, 0.4% of these samples contained concentrations (10^2–10^6 CFU/g) of *Vibrio parahaemolyticus* exceeding European Commission recommendations.[20] A study of blue mussels grown in German waters detected the presence of *Vibrio* species in about 74% of the samples.[21] The most common *Vibrio* species was *V. alginolyticus* (51.2% of *Vibrio* isolates) followed by *V. parahaemolyticus* (39.5%) and *V. vulnificus* (3.5%).

Food Processing

Cholera has been virtually eliminated from developed countries as a result of improvements in sanitation, sewage management, water delivery, and water treatment, which effectively control *V. cholerae*.[22] Proper cooking and refrigeration of seafood are the most effective means of controlling *V. cholerae* and *V. parahaemolyticus*.[15] Transmission of *V. parahaemolyticus* occurs in restaurants from the contamination of utensils and food preparations surfaces with organisms from raw food or the handling of cooked food with contaminated hands. To prevent the rapid increase in *V. parahaemolyticus* in shellfish, harvested clams and oysters should be rapidly refrigerated during transport, processing, and storage at temperatures below 50 °F (10 °C). Boiling water for 10 minutes inactivates *V. cholerae*.[23]

TOXINS

Physiochemical Properties

Vibrios tolerate a wide range of alkaline pH (i.e., up to 8.5–9.5) and salty habitats, allowing them to thrive in surface waters.[24] Gastric acid readily destroys *V. cholerae*, and therefore patients with decreased gastric acid production are more susceptible to cholera.[25] Alkaline pH and resistance to bile salts enable *Vibrios* to survive in the small intestine.[26] Most *Vibrios* possess a heat-labile, flagellar H antigen that governs bacterial motility. Over 140 serogroups of *V. cholerae* occur worldwide, but only three serogroups, *V. cholerae* O1, O139, and 0141, produce cholera toxin (CAS RN: 9012-63-9).[27] *V. cholerae* O1 variably expresses surface antigens that define two serotypes: Inaba (antigens A and B) and Ogawa (antigens A and C). A third serotype, Hikojima, is a transitional serotype of *V. cholerae* O1 (antigens A, B, and C) that allows the organism to shift between the Inaba and Ogawa serotypes during the life cycle.[28] *V. cholerae* O1 serotypes are further differentiated by morphologic properties into the classical biotype and the El Tor biotype. The former biotype is lysed by classical IV and FK bacteriophages and inhibited by polymyxin B, whereas the latter biotype causes *in vitro* hemolysis, erythrocyte agglutination, and a positive Voges-Proskaur test.[29] The latter test is positive as a result of the bacterial conversion of glucose to acetyl methylcarbinol. *V. cholerae* O1 does not possess a capsule; thus, this organism does not spread beyond the intestine. *V. vulnificus* possesses an acid polysaccharide capsule that promotes dissemination and systemic infection.[30] *Vibrio vulnificus* is a natural contaminant of warm seawater (>20 °C/68 °F) and low salinity (<1.6%).[31] In a study of 34 virulent stains of *V. parahaemolyticus* isolated from coastal waters off Oregon and Washington, there were six O serotypes (O1, O3, O4, O5, O10, and O11) as measured by pulsed-field gel electrophoresis.[32] The most common serotypes were O5 (19 isolates) and O1 (9 isolates).

Mechanism of Toxicity

Vibrio cholerae O1 causes diarrhea via the following five virulence factors: toxin coregulated pili, neuramidase, accessory cholera enterotoxin, zonula occludens toxin, and cholera toxin (CT). *Vibrio cholerae* adheres to microvilli of the brush border of gastrointestinal epithelial cells via toxin coregulated pili, which enable the organism to remain attached during extensive diarrhea (up to 20–30 L/d).[33] Neuramidase enhances binding of cholera toxin to epithelial cells in the intestinal wall by degrading membrane polysialosyl gangliosides into the monosialosyl ganglioside (GM-1), which is a specific receptor for cholera toxin.[34,35] The *V. cholerae* genome contains multiple copies of genes coding for accessory cholera enterotoxin, which enhances chloride secretion and impairs sodium and chloride absorption,[36] whereas zonula occludens toxin relaxes epithelial cell tight junctions.[37] Cholera toxin is encoded on a bacteriophage (CTXΦ). CTXΦ first binds to toxin coregulated pili, which subsequently incorporates

CTXΦ into the *V. cholerae* genome for transcription.[38] Cholera toxin is structurally and functionally identical to the heat-labile toxin (LT) of enterotoxigenic *Escherichia coli* (ETEC).[39] Cholera toxin is composed of an A subunit (28 kDa) linked to a ring of five B subunits (12 kDa each) by a disulfide bridge, and both units are necessary for the production of gastrointestinal illness.[40] The A subunit consists of the virulent enzymatic piece (A1 peptide), and the bridge from A1 to the B ring (A2 peptide). The B subunit ring binds to the GM-1 ganglioside of the intestinal epithelial cell, and the epithelial cell internalizes the A subunit. Lipid rafts carry the intact toxin to the endoplasmic reticulum, where protein disulfide isomerase splits the A subunit into A1 and A2.[41] A1 then diffuses into the cytosol. Subunit A1 activates regulatory G_s proteins by blocking the hydrolysis of GTP to GDP, which permanently activates adenyl cyclase for the life of the epithelial cell.[42] Adenyl cyclase breaks down intracellular ATP into the intracellular messenger cyclic AMP (cAMP). Cyclic AMP accumulates along the cell membrane where it activates protein kinase A, resulting in phosphorylation of ion transport channels and secretion of sodium, chloride, potassium, bicarbonate, and water into the intestinal lumen.[43] Not all strains of *V. cholerae* O1 elaborate enterotoxin, resulting in asymptomatic colonization in human hosts.[44] The mechanism of toxicity of *Vibrio cholerae* O139 and *Vibrio cholerae* O1 is identical.[45] *Vibrio parahaemolyticus* produces a thermostable direct hemolysin (TDH), which increases intracellular calcium and chloride ion secretion by epithelial cells.[46] A polysaccharide capsule confers antiphagocytic state to *V. vulnificus*, permitting systemic invasion and proliferation mediated by siderophores, cytolysins, and collagenase.[47]

DOSE RESPONSE

The infective dose of *V. cholerae* or *V. parahaemolyticus* is relatively high (10^{11} organisms) in drinking water because of the destruction of most of these organisms by the acidic environment of the stomach.[48] The buffering capacity of food reduces the inoculum threshold to 10^4 to 10^6 organisms, whereas patients with achlorhydria require as few as 10^3 organisms to cause illness.[49,50] The symptoms associated with cholera are more severe in patients with blood group O than with other blood types.[51] The mortality rate of cholera is approximately 1% in adequately treated patients compared with about 60% in untreated patients.[52] As few as 100 organisms may cause septicemia following the ingestion of food contaminated by *V. vulnificus*.[53] The infective dose of *V. parahaemolyticus* probably is >100,000 CFU.[54]

CLINICAL RESPONSE

The incubation period for *V. cholerae* is about 1–4 days, and during this time the bacteria proliferate and elaborate enough enterotoxin to produce clinical effects.[48] The severity of the gastrointestinal symptoms depends on the size of the inoculum, the extent of cholera toxin production, and the classical biotype.[44] About 60% of exposures to *V. cholerae* are asymptomatic. In symptomatic cases, diarrhea begins abruptly with massive watery fluid interspersed with mucus and epithelial tissue ("rice-water" stools). Nausea, vomiting, bloating, cramping abdominal pain, and low-grade fever are commonly associated clinical findings. Patients may lose up to one liter of fluid per hour.[48] Profound dehydration may cause anuria, hypovolemia, shock, and cardiovascular collapse. Hypernatremic or hyponatremic dehydration and severe acidosis may cause mental status changes and seizures, while hypokalemia may cause cardiac arrhythmias. The illness resolves within 1–5 days when treated.[55] The clinical courses of infections with *V. cholerae* O139 and *V. cholerae* O1 are similar.[56] *Vibrio parahaemolyticus* causes milder, self-limited gastrointestinal symptoms lasting 1–3 days, with bloody diarrhea in 25% of reported cases.[57] The mean incubation period for *Vibrio parahaemolyticus*-induced illness is about 15 hours with a range of 4 to 96 hours.[58] *Vibrio vulnificus* causes mild gastroenteritis with or without blood, followed by systemic invasion and septicemia.[59]

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect *V. cholerae* in stool include the oxidase test, Kligler iron agar, triple sugar agar, Gram stain, string test, and wet mount. After isolation of the bacteria, the use of antiserum allows the determination of serogroup and type. Phase-contrast and darkfield microscopy of *Vibrio* species demonstrate curved, motile, gram-negative rods.[60] The addition of anti-*V. cholerae* O1 antiserum (monoclonal or polyclonal antibodies) to the microscopy slide instantly halts motility in about 50% of examinations, and this technique quickly differentiates *V. cholerae* 0139 from other motile rods such as *Campylobacter*.[61] Vibrios grow poorly on MacConkey agar, but these bacteria grow readily in thiosulfate-citrate-bile salts-sucrose (TCBS) agar that is pre-enriched in alkaline (pH 8.5) peptone broth.[62] Stool samples typically carry 10^7 to 10^8 organisms, and thus stool cultures rarely require pre-enrichment. Food and water samples carry fewer organisms, often necessitating pre-enrichment for investigation of *Vibrio*-related foodborne or waterborne illnesses.[63] A positive oxidase

test quickly differentiates *Vibrio* species from isolated colonies of enteric bacteria.[64] Serotyping via anti-O group antisera is reserved for epidemiologic investigations.[65] Polymerase chain reaction (PCR) provides rapid identification of as few as three organisms of cholera toxin-producing strains in broth cultures[66] and in food samples.[67] Because of the prevalence of numerous nonpathogenic *Vibrio* species, identification of these bacteria in stool or in food samples must be followed by confirmation of cholera toxin production.[68] *Vibrio parahaemolyticus* and *V. vulnificus* are identified by similar methods.[69–71] *Vibrio parahaemolyticus* thermostable direct hemolysin is detected by immunochromatographic assay.[72] AOAC (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) official method of analysis 988.20 determines the presence of *Vibrio cholera* in oysters.[73] AOAC official method 994.06 identifies *Vibrio vulnificus* by gas chromatographic examination of microbial fatty acid profile.

Biomarkers

Vibrio cholerae does not enter the blood, but these bacteria produce a transient serum antibody response that peaks 8–10 days after infection. This response resolves within 2 months.[74]

Abnormalities

Severe fluid and electrolyte losses cause hypernatremia (serum Na > 150 mEq/L) or hyponatremia (serum Na < 130 mEq/L), hypokalemia (serum K < 3.0 mEq/L), hypochloremia, elevated urine specific gravity (SpG > 1.020), and hyperphosphatemia. Low serum bicarbonate results from lactic acid production or elevated bicarbonate secondary to contraction alkalosis. ST-T flattening and arrhythmias may be observed on electrocardiogram.

TREATMENT

Treatment includes rehydration and bowel rest. Extreme fluid losses from the gastrointestinal tract necessitate aggressive rehydration with fluid and electrolytes. Oral rehydration is usually sufficient in mild to moderate cases, but intravenous fluid replacement and hospitalization may be necessary in cases of severe dehydration or electrolyte abnormalities, particularly in young children or elderly patients.[75,76] In 1991, the World Health Organization achieved a 99% survival rate in 300,000 patients in Peru with a cholera treatment plan using powdered formulations reconstituted into oral rehydration solutions.[77] Antimicrobial therapy may curtail toxin production, reduce stool output, decrease bacterial shedding in epidemics, and shorten illness duration in severe cases; however, antimicrobials are minor adjuncts to fluid replacement therapy.[78] Children are treated with trimethoprim-sulfamethoxazole; adults are treated with tetracycline or doxycycline.[79] Prophylaxis with tetracycline may reduce infection rates in travelers to endemic areas,[80] but plasmid-mediated, tetracycline-resistant strains are prevalent in endemic areas.[81,82] Production of IgA antibodies to *V. cholerae* O1 follows infection with predictable protection from future exposures for up to 3 years; however, immunity to *V. cholerae* O1 does not confer immunity to *V. cholerae* O139 or other *Vibrio* species.[83] Maternal antibodies from breast milk protect young infants in endemic regions.[84]

Chapter 24

YERSINIA ENTEROCOLITICA

CYRUS RANGAN, MD, FAAP

HISTORY

Yersinia enterocolitica subsp. *enterocolitica* (Schleifstein & Coleman) Frederiksen (*Y. enterocolitica*) is a nonlactose fermenting, gram-negative, facultatively anaerobic, urease-positive, oxidase-negative coccobacillus. The US microbiologists J.I. Schleifstein and M.B. Coleman first cultured foodborne *Y. enterocolitica* in 1939; they named this bacterium after the Swiss bacteriologist Alexandre J. Yersin, who discovered the cause of plague (*Yersinia pestis*).[1] The first major US outbreak of foodborne *Yersinia* gastroenteritis occurred in 1976 in Holland Patent, New York, where 222 children developed gastroenteritis and mesenteric lymphadenitis from chocolate milk contaminated with *Y. enterocolitica* serotypes O:5 and O:8.[2] *Yersinia pseudotuberculosis* subsp. *pseudotuberculosis* (Pfeiffer) Smith and Thal is a rare cause of bacterial food poisoning in humans.[3]

EXPOSURE

Source

Yersinia enterocolitica is an extremely heterogeneous species that is divided into six biogroups (1A, 1B, 2, 3, 4, and 5). Biogroups 2, 3, and 4 are more common in Europe, whereas biogroup 1B occurs primarily in North America and biogroup 1A has a separate, unknown origin.[4] All of these biogroups are pathogenic to human hosts with the possible exception of biogroup 1A, which lacks virulent plasmids (pYV), chromosomal invasion-associated genes (*ail, inv*), and the heat-stable enterotoxic *ystA* gene present in the other virulent biotypes. However, the production of enterotoxin *ystB* by 1A strains suggests that this biotype can cause gastroenteritis in humans.[5,6] Each biogroup contains several serotypes. Bioserotypes 1B/O:8, 2/O:5,27, 2/O:9, and 4/O:3 are responsible for the majority of human infections including all major worldwide outbreaks since 1976.[7] Serotypes are not necessarily unique to pathogenic species as the O:3 antigen exists in biovar 1A and nonpathogenic *Yersinia* species (e.g., *Y. frederiksenii* Ursing, *Y. kristensenii* Bercovier).[8] Most cases of yersiniosis in humans occur sporadically without an apparent source; foodborne outbreaks of gastroenteritis caused by *Yersinia* species are rare.[9] The prevalence of yersiniosis is particularly high in Europe, where the high prevalence of *Y. enterocolitica* O:3/O:9-specific antibodies in healthy blood donors suggest the possibility of a high rate of subclinical yersiniosis in healthy populations.[10] *Y. enterocolitica* proliferates at 4 °C (39 °F), and therefore high bacterial loads (10^6–10^9 CFU/mL) develop in blood products refrigerated over 21 days.[11] Additionally, the presence of anticoagulant-preservative and hemoglobin from lysed red blood cells promote the growth of this bacterium.

ENVIRONMENT

Animal feces contaminate soil, water, fertilizers, and effluents with *Yersinia* worldwide, especially in colder regions such as Scandinavia and Canada.[12]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Animal

Yersinia enterocolitica causes minor, self-limited disease and lifelong asymptomatic carriage in pigs, cattle, deer, sheep, seafood, birds, and reptiles. Of these animals, pigs are a major reservoir of pathogenic *Y. enterocolitica* with prevalence of pathogenic *Y. enterocolitica* in stool samples being approximately 10–15%.[13] Most animals carry nonvirulent *Yersinia* species of biogroup 1A. However, the indistinguishable genotypes in human strains of *Y. enterocolitica* and strains in dogs, cats, sheep, and rodents suggest that these animals also may be sources of human yersiniosis.[9] In a study of 2,349 pigs from eight US swine operations, 120 (5.1%) of the pigs were positive for pathogenic *Y. enterocolitica*, as measured by the presence of attachment-invasion locus factor (Ail) with multiplex polymerase chain reaction (PCR).[14]

Food

Yersinia may contaminate drinking water, pork products, meat, poultry, and unpasteurized dairy products.[15,16] *Yersinia enterocolitica* serotypes O:5 (biogroup 1B), O:8 (biogroup 2), and O:9 (biogroup 4) are commonly involved with human foodborne infections, primarily from raw pork and dairy products.[9] The incidence of *Y. enterocolitica* contamination in ready-to-eat food products (e.g., pork) is relatively low.[17] Most human infections originate from undercooked pork, tofu, and unpasteurized dairy products; vegetable and soy products may harbor *Y. enterocolitica* after washing with contaminated water during food manufacturing and handling.[18]

Food Processing

The most effective controls of *Yersinia* contamination include the following methods: proper cooking and refrigeration, purification of water, pasteurization of dairy products, separation of cooked and uncooked foods, sanitation of food preparation surfaces with at least 1% bleach solution, washing of vegetables, and cooking foods to 120 °C–170 °C (248 °F –338 °F).[19] *Yersinia enterocolitica* proliferates readily at refrigeration temperatures. Hence, refrigeration does not effectively control the growth.[20]

TOXINS

Physiochemical Properties

Yersinia enterocolitica is one of five common, foodborne bacterial gastrointestinal pathogens, which include non-typhoid *Salmonella, Shigella* species, diarrhea-producing *E. coli*, and *Campylobacter* species.[21] The genus *Yersinia* contains 12 species (*Y. aldovae, Y. aleksiciae, Y. bercovieri, Y. enterocolitica, Y. frederiksenii, Y. intermedia, Y. kristensenii, Y. mollaretii, Y. pestis, Y. pseudotuberculosis, Y. rohdei*, and *Y. ruckeri*). These bacteria are gram-negative, nonspore-forming, rod-shaped, facultative anaerobes.[22] Only *Y. pestis, Y. pseudotuberculosis, and Y. enterocolitica* are pathogenic to healthy humans, whereas other species occur rarely as opportunistic infections.[23] Of these pathogenic bacteria, *Y. enterocolitica* is the most important cause of foodborne illness.[24] *Yersinia enterocolitica* grows over a wide temperature range (1 °C –45 °C/34 °F–113 °F), and thus this bacterium proliferates under refrigeration (0 °C–4 °C/32 °F–39 °F), room temperature (20 °C–25 °C/68 °F–77 °F), and human body temperature (37.0 °C/98.6 °F).[25,26] *Y. enterocolitica* grows optimally at 25 °C (77 °F), and under these conditions the organism expresses chromosomally derived virulence determinants. These determinants allow the bacterium to maintain a coccidial, hydrophilic morphology and high motility; thus, enhancing survival at room temperature. At human body temperature (37.0 °C/98.6 °F), *Y. enterocolitica* becomes a pleomorphic, nonmotile, hydrophobic organism, which synthesizes virulence determinants from a 70-kbp plasmid (pYV). These determinants promote intestinal proliferation and invasion of human cells by *Y. enterocolitica*.[27] Table 24.1 lists the virulence determinants expressed by *Y. enterocolitica* at these temperatures.

Mechanism of Toxicity

Yersinia enterocolitica synthesizes both chromosomal and plasmid-encoded virulence factors that mediate colonization, host cells invasion, and resistance to host defenses. Some synthesized factors have multiple functions.[28] At room temperature (25 °C/77 °F), *Y. enterocolitica* synthesizes chromosomally encoded factors, including membrane surface proteins [invasin (Inv), attachment-invasion locus factor (Ail)][29,30] and flagellae. Expression of the latter factor allows the bacterium to travel through the stomach and small intestine after ingestion.[31] As *Y. enterocolitica* adapts to human body

TABLE 24.1. Virulence Factors Expressed by *Yersinia Enterocolitica* at 25 °C (77 °F) and 37.0 °C (98.6 °F)

25 °C/77 °F	37.0 °C/98.6 °F
Flagella	Adhesion factor (YadA)
Invasin (Inv)	Secreted effectors (Yops proteins)
Attachment-invasion locus factor (Ail)	V-antigen

Source: From Ref 27.

temperature (37.0 °C/98.6 °F), the bacterium synthesizes temperature-inducible, plasmid-encoded membrane surface proteins. The first synthesized protein, YadA, adheres preferentially to the mucus layer overlying the ileocecal brush border.[32] Chromosomally encoded Inv and Ail bind to B1 integrins on the surfaces of lymphofollicular M cells in Peyer's patches, initiating invasion of M cells, and facilitating delivery of microcolonies of *Y. enterocolitica* into adjacent tissues.[33] Plasmid-encoded V-antigen induces interleukin-10 (IL-10) release, which suppresses macrophage-derived tumor necrosis factor-alpha (TNF-α), an important inflammatory mediator and chemoattractant.[34] V-antigen further mediates bacterial resistance to host defenses by translocating several plasmid-encoded virulence effectors (Yops) via a Type III secretion system.[35,36] These Yop effectors (YopE, YopT, YopO) disrupt the actin skeleton of macrophages and synergistically increase the resistance of the bacteria to phagocytosis by macrophages and polymorphonuclear leucocytes.[37] YopH (a tyrosine phosphokinase) inhibits phagocytosis by dephosphorylating $p130_{cas}$, a macrophage signal transduction protein.[38] YopJ prevents formation of activated nuclear factor-κB (NF-κB), by blocking the mitogen-activated protein kinase (MAPK) cascade; NF-κB regulates macrophage production of proinflammatory cytokines, intercellular adhesin molecule 1, and E selectin. Down-regulation of these inflammatory signal pathways activates macrophage apoptosis.[39] Proliferation in the ileocecal mucosa and evasion of phagocytosis enable *Y. enterocolitica* to form microabscesses and ulcers in the mucosa. These processes destroy the architecture of Peyer's patches and promote inflammation, fluid secretion, blood loss, and diarrhea.[40] *Yersinia enterocolitica* invades the lamina propria (i.e. enteritis, enterocolitis, terminal ileitis), and the infection extends to regional lymphoid tissue (i.e., mesenteric lymphadenitis) or systemically through the blood (i.e., septicemia).[41] Outer membrane proteins YadA and Ail confer resistance to serum bactericidal activity by binding complement proteins and preventing membrane attack complex (MAC) assembly.[42] *Yersinia enterocolitica* produces a plasmid-encoded heat-stable enterotoxin (Yst) that is similar to enterotoxigenic *E. coli* (ETEC) heat-stable toxin. However, Yst is only mildly toxic to the gastrointestinal tract. This enterotoxin enhances the persistence of the organism after systemic invasion, thus facilitating spread of the bacteria to other organs and long-term shedding after infection.[43] *Yersinia enterocolitica* secretes yersiniabactin, an iron-complexion siderophore, which promotes bacterial growth in iron-rich environments; patients with iron overload are at increased risk of developing *Y. enterocolitica* septicemia.[44] *Yersinia enterocolitica* expresses a natural receptor for desferrioxamine on the outer membrane called FoxA, which transports the iron-desferrioxamine complex into the cell; thus, patients undergoing therapy with desferrioxamine are also at increased risk of developing septicemia.[45,46] HLA-B27-positive patients may harbor persistent *Yersinia* antigens, which suppress T-cells and TNF-α, leading to autoimmune sequelae such as reactive arthritis.[47] Autoimmune sequelae are more prevalent with infection with *Y. enterocolitica* serotype O:3 phage type 8. Immune-mediated response to *Yersinia* antigens probably causes some of the cases of chronic undifferentiated arthritis due to the formation of *Yersinia* antigens in colonic and synovial tissues.[48]

DOSE RESPONSE

The amount of inoculum of *Y. enterocolitica* required to produce disease is unknown because host defenses destroy a significant portion of the inoculum before bacteria reach the distal ileum, adhere to the mucosa, and synthesize plasmid-encoded resistance factors. The estimated size of inoculum for clinical infection based on rabbit models is 1.6×10^{10} CFU.[49] *Yersinia enterocolitica* serotype O:8 produces more severe symptoms than other serotypes.[50] *Yersinia enterocolitica* biogroup 1A bacteria are generally nonpathogenic, but may become opportunistic nosocomial pathogens in neonates or immunocompromised hosts.[51]

CLINICAL RESPONSE

Although *Yersinia enterocolitica* gastroenteritis occurs predominately in children, this organism is an uncommon cause of gastroenteritis in this age group compared with viruses and other bacteria (e.g., *E. coli, Salmonella, Shigella, Campylobacter*). In a prospective cohort study of children presenting to a pediatric emergency department with diarrhea and providing a stool sample, *Y. enterocolitica* was detected in 2 of 372 specimens testing positive for a pathogen.[52] *Y. enterocolitica* incubates for 1–2 days before the development of gastrointestinal symptoms, primarily diarrhea in infants and young children. Initial gastrointestinal signs and symptoms include low-grade fever, chills, malaise, sharp or cramping abdominal pain, and watery or bloody diarrhea with vomiting occurring in 40% of cases.[53] Children under 5 years of age typically present with enterocolitis, sharing many clinical characteristics with inflammatory bowel disease, whereas children over 5 years and young adults present with acute mesenteric lymphadenitis or terminal ileitis.[54] Infrequently, patients with acute mesenteric lymphadenitis or terminal ileitis complain of pain and tenderness localized to the right lower abdominal quadrant, mimicking acute appendicitis. This pseudoappen-

dicitis typically occurs in older children and adolescents.[55] Septicemia occurs primarily in immunocompromised patients or young infants, patients with iron overload or undergoing therapy with desferrioxamine, or in immunocompromised patients with transfusion-transmitted infections.[56,57] Mortality rate in cases of *Y. enterocolitica* septicemia is approximately 35–50%, depending on the underlying health of the patients.[58] Liver and spleen abscesses, meningitis, encephalitis, pneumonia, endocarditis, osteomyelitis, or septic arthritis may complicate septicemia in high-risk patient groups.[59–64] Sequelae include reactive arthritis, erythema nodosum, uveitis, and Reiter's syndrome (arthritis, conjunctivitis, urethritis) 1–2 weeks after recovery in 1–2% of patients; 80% of patients with sequelae are positive for HLA-B27. These postinfection complications occur primarily in young adults. Reactive arthritis is more common following infections by *Y. enterocolitica* and *Salmonella* species than *Campylobacter* species.[21] Case reports suggest that the arthritic symptoms last at least 2–4 months.[65] Circumstantial evidence suggests that *Yersinia* infections initiate or exacerbate chronic inflammatory bowel disease (ulcerative colitis, Crohn's disease).[66]

DIAGNOSTIC TESTING

Analytical Methods

Yersinia enterocolitica grows readily on most routine enteric media such as MacConkey agar; slowly on Hektoen-enteric and xylose-lysine-deoxycholate agars; and poorly on *Salmonella-Shigella* agar. However, conventional culture-dependent methods are slow and *Y. enterocolitica* colonies on these media are small and difficult to distinguish visually from normal flora and other pathogenic bacteria.[67] Laboratories should be specifically requested to evaluate the specimen for *Y. enterocolitica. Yersinia enterocolitica*-selective cefsulodin-Irgasan (triclosan, CAS No: 3380-34-5)-novobiocin agar (CIN-agar) inhibits the growth of normal flora and isolates *Y. enterocolitica* as "bull's-eye" colonies with dark pink-to-red centers and clear borders.[68] Cold preenrichment of specimens at 4 °C (39 °F) in phosphate-buffered saline may enhance *Y. enterocolitica* growth before culture, but this method requires extended incubation time up to 21 days. This method also enhances the growth of normal flora and other pathogenic organisms, whereas incubation of CIN-agar plates at 25 °C (77 °F) for 18–20 hours effectively and rapidly isolates *Y. enterocolitica* from other bacteria.[69]

Molecular (DNA-based) methods allow the amplification of specific genetic signals from a few cells, and therefore these analytical methods are much more sensitive and specific than the use of selective microbiological media. Polymerase chain reaction (PCR) is the most common nucleic acid amplification technique for the diagnosis of infectious diseases. This method detects pYV-positive organisms both in live and dead strains of *Y. enterocolitica*, and PCR for this bacterium yields 99% specificity and 100% sensitivity.[70,71] Because of the possible loss of plasmids, real-time PCR methods also target chromosomal virulence genes (*ail, inv, yst*) in the chromosome of pathogenic *Y. enterocolitica* strains. Subtyping procedures are useful for tracking individual strains responsible for outbreaks of *Y. enterocolitica*. Analytical methods for subtyping include the older phenotypic subtyping, such as biogrouping (biochemical properties), antibiotic susceptibility, serotyping (O and H antigens), phage typing (bacteriophage lysis patterns), and esterase typing. Newer genotypic subtyping includes pulsed-field gel electrophoresis, multilocus enzyme electrophoresis, ribotyping, PCR-based subtyping techniques, amplified fragment length polymorphism, PCR-restriction fragment length polymorphism, repetitive element PCR, and DNA sequencing-based subtyping techniques (multilocus sequence typing). Conventional PCR assays typically require lengthy enrichment and DNA-extraction protocols, whereas real-time PCR relies on cleavage of a fluorogenic probe for detection of amplicons. Real-time PCR is 100% specific to virulent *Y. enterocolitica* with a limit of sensitivity near 10^3 CFU/mL in stool samples and an assay time of 1.5 days.[72] These subtyping techniques are reserved for the investigation of epidemics.

Biomarkers

Analysis of serum antibodies to *Yersinia* antigens helps differentiate acute from chronic *Yersinia* infections. IgM-class antibodies are associated with acute infections, whereas IgA and IgG antibodies develop as the disease progresses. Serum IgA antibodies to lipopolysaccharide (LPS or "O" antigen) persist for several months after the onset of *Yersinia* infections, particularly in patients with reactive arthritis after exposure to serotype O:3.[73,74]

Abnormalities

Leukocytosis with or without left shift occurs during gastroenteritis, acute mesenteric lymphadenitis, and septicemia. Fecal leukocytes and red blood cells (with or without frank blood) are commonly observed on light microscopy. Severe dehydration involves hypernatremia (serum Na > 150 mEq/L) or hyponatremia (serum Na < 130 mEq/L), hypokalemia (serum K < 3.0 mEq/L), hypochloremia, elevated urine specific gravity (SpG > 1.020), and hyperphosphatemia. Low serum bicarbon-

ate results from lactic acid production or elevated serum bicarbonate secondary to contraction alkalosis. Computed tomography helps distinguish true appendicitis from pseudoappendicitis caused by *Y. enterocolitica*.[75]

TREATMENT

Treatment of *Yersinia* infection includes bowel rest with fluid and electrolytes replacement. Gastrointestinal manifestations and associated flu-like symptoms of *Yersinia* gastroenteritis rarely require hospitalization, and these effects generally resolve spontaneously in 3–10 days.[53] Oral replacement may be sufficient, but affected patients may experience significant anorexia, necessitating intravenous fluid replacement and hospitalization in cases of significant dehydration or severe electrolyte abnormalities, particularly in young children or elderly patients.[76,77] Patients with severe cases of enterocolitis, septicemia, acute mesenteric lymphadenitis, or disseminated disease require prompt antimicrobial therapy.[78] *Yersinia enterocolitica* synthesizes β-lactamases, rendering most strains resistant to penicillins and first- and second-generation cephalosporins.[79] Combined therapy with a third-generation cephalosporin (e.g., cefotaxime, ceftriaxone) plus an aminoglycoside (e.g. gentamicin) is appropriate empiric treatment pending susceptibility studies, as rare cases of antimicrobial resistance have emerged with these medications.[80] Fluoroquinolones (e.g., ciprofloxacin) may be utilized in adult patients with confirmed susceptibilities.[81] Pseudoappendicitis may be difficult to distinguish from true appendicitis, resulting in surgical exploration.

Chapter 25

CYANOBACTERIA

HISTORY

Cyanobacteria are ancient inhabitants of brackish-, marine- and fresh-waters as well as terrestrial environments. They were the first organisms capable of converting carbon dioxide to oxygen via photosynthesis, and fossil records indicate these primitive organisms existed 3.3–3.5 billion years ago.[1] Consequently, cyanobacteria probably contributed to the formation of oxygen in the atmosphere.[2] Eutrophication of freshwater by industrial and agricultural effluent during warm periods in the late summer and fall promotes the growth of blooms or scum containing toxin-producing cyanobacteria. Accounts of these blooms date back to the 12th century AD when a scum occurred on Llangorse Lake in Wales.[3] In 1878, Francis documented the death of Australian livestock from the ingestion of water from a heavily contaminated lake that probably contained a bloom of cyanobacteria.[4] Cyanobacteria are a suspected cause of Barcoo fever, which is an acute gastrointestinal illness documented in the outback of northern Australia since the late 1800s.[5] In 1931, a massive bloom of *Microcystis* species in the Ohio and Potomac Rivers was associated with gastrointestinal illness in persons using drinking water from these sources.[6] In 1979, a gastrointestinal illness, subsequently called Palm Island mystery disease, resulted in the hospital admission of over 100 children from Aboriginal families. This mystery illness was later causally linked to cylindrospermopsin-producing stain of the cyanobacterium, *Cylindrospermopsis raciborskii* (Woloszynska) Seenayya et Subba Raju, which was present in the water supply at nearby Solomon Dam.[7] A chronic neurodegenerative disease of the indigenous Chamorro people of Guam has been associated with the production of the neurotoxic nonprotein amino acid, β-methylamino-L-alanine (BMAA), by cyanobacteria.[8] Biomagnification of this neurotoxin occurs when the roots of the cycad tree absorbs BMAA from the symbiotic cyanobacteria and concentrate the BMAA in the cycad seeds. The indigenous Chamorro people are exposed to BMAA when they eat flying foxes that feed on these seeds. An amyotrophic lateral sclerosis/Parkinsonism dementia complex develops in these people, sometimes decades after exposure to BMAA.

In 1996, 131 dialysis patients in Caruaru, Brazil, were exposed to microcystins in dialysis fluid as a result of contamination of the water used for their hemodialysis.[9] Most of these patients developed nausea, vomiting, and visual disturbances. Acute liver failure developed in 110 of these patients, and by the end of the year, 60 of these patients died.

EXPOSURE

Toxic cyanobacteria occur in numerous brackish, coastal, and marine environments as well as in freshwater of over 45 countries.[10] There are about 500–1,500 species and 40 genera of primitive photosynthetic microorganisms from the phylum Cyanobacteria.[11] Other common names of these simple microorganisms include blue-green algae or pond scum.[1] Although photosynthesis occurs both in cyanobacteria and in true algae, cyanobacteria are gram-negative, prokaryotic, single-cell organisms with no membrane enveloping their nuclear

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

material or membrane-bound, interior bodies. These organisms probably do not invade or colonize animal or human tissues. Algae are more complex eukaryotic cells containing a definite nuclear membrane and internal organelles (e.g., mitochondria). True algae also form blooms, particularly in freshwater with abundant supplies of phosphorus and dissolved nitrogen in the form of nitrate or ammonia. As nitrogen supplies become limited (e.g., after an algal bloom) the growth of cyanobacteria is favored because these microorganisms fix nitrogen from the atmosphere.[11] Like certain other chemicals (alkaloids, phenols, sterols, tannins) in vascular plants, the toxins present in cyanobacteria probably provide some protection against feeding by other organisms (e.g., zooplankton).

Source

Environment

Cyanobacteria release large amounts of blue-pigmented proteins (phycobiliproteins) during lysis, and these organisms were originally called blue-green algae. Although the photosynthetic apparatus of cyanobacteria and algae is similar, these organisms are genetically distinct and cyanobacteria are classified as bacteria. Most toxin-producing cyanobacteria are free-floating (planktonic) columns or filaments present in freshwater lakes, stagnant water, and slow-moving streams. Many planktonic cyanobacteria possess specialized, intracellular gas vesicles that allow adjustment of their buoyancy and their depth in the water. Thus, these bacteria can overcome the spatial separation of deep nutrient layers in the water and light at the surface of the water. During the beginning of summer, a variety of cyanobacteria and eukaryotic algae coexist in lakes. However, this diversity typically decreases dramatically during the end of summer following the development of a bloom of one particular species from the phylum Cyanobacteria.[12] Cyanobacteria also grow on moist terrestrial surfaces and on the surface of water as dense, benthic mats.[13] Table 25.1 lists the types of cyanobacterial populations seen in fresh and marine waters as well as the cyanobacterial genera commonly observed in these masses. Some species from the phylum Cyanobacteria are adapted to particular environments including species of *Anabaena* (freshwater lakes with limited nitrogen supplies), *Nodularia* (brackish and estuarine environments), and *Planktothrix* (turbid shallow lakes, thermally stratified lakes).[12]

Conditions that favor the growth of cyanobacteria include low wind velocity, warm temperatures (15 °C–30 °C/59 °F–86 °F), pH 6–9, and abundant sources of nitrogen and phosphorus.[1] The concentration of cyanobacterial toxins varies with season, conditions, and dominant species. In a study of German lakes and reservoirs, the highest microcystin concentrations occurred in waters dominated by *Planktothrix rubescens* (D.C. *ex* Gomont) Anagnostidis and Komárek and *Planktothrix agardhii* (Gomont) Anagnostidis and Komárek.[14] Median total microcystin content per biomass (mg/g dry weight) of water samples dominated by these two species were 2.0 (range: 1.03–5.6) and 1.46 (range: 0.19–3.6), respectively.

The most common toxin-producing cyanobacteria belong to the following genera: *Anabaena* (anatoxin-a), *Cylindrospermopsis* (cylindrospermopsin, saxitoxins), *Lyngbya* (lyngbyatosin), *Microcystis* (microcystins), *Nodularia* (nodularins), and *Oscillatoria* (anatoxins, microcystins).[11]

Surface-dwelling, scum-forming genera include *Anabaena*, *Aphanizomenon*, *Nodularia*, *Microcystis*, whereas the genera *Cylindrospermopsis* and *Oscillatoria* are subsurface bloom-formers.[15] Table 25.2 lists some of the recognized toxin-producing cyanobacteria. Most exposures to toxin-producing cyanobacteria occur in lakes, rivers, and ponds of the great plains of North America and Australia. Genera from the phylum Cyanobacteria associated with toxic blooms in eutrophic Scandinavian lakes included *Anabaena, Aphanizomenon, Gomphosphaeria, Microcystis, Nodularia*, and *Oscillatoria*.[16] The disagreeable color and odor of scum in freshwater discourages human consumption, but symptoms may result from exposure during water-related activities

TABLE 25.1. Observable Types of Cyanobacterial Mass Populations

Type	Toxin-Producing Genera	Description
Blooms	Anabaena, Anabaenopsis, Aphanizomenon, Cylindrospermopsis, Microcystis, Nodularia, Planktothrix	Present throughout water column secondary to buoyancy-regulating properties
Scums	Anabaena, Anabaenopsis, Aphanizomenon, Microcystis, Planktothrix	Accumulate at surface in calm waters secondary to rapid increase in cyanobacterial buoyancy
Mats/Biofilms	Lyngbya, Oscillatoria, Phormidium	Grow on surface of sediment and rocks near water edge

TABLE 25.2. Some Toxin-Containing Species of Cyanobacteria

Species
Anabaena flos-aquae (Lyngbye) Brébisson ex Bornet & Flauhault
Anabaena lemmermannii forma *laxa* (Skuja) G. Cronberg & J. KomÃirek
Anabaena torulosa Lagerheim ex Bornet & Flahault
Aphanizomenon ovalisporum Forti
Aphanocapsa incerta (Lemmermann) Cronberg & Komárek
Coelosphaerium kuetzingianum Naegeli
Cylindrospermopsis raciborskii (Woloszynska) Seenaya & Subba Raju
Gloeotrichia echinulata
Lyngbya birgei Smith
Lyngbya majuscula (Dillwyn) Harvey
Microcystis aeruginosa (Kützing) Kützing
Microcystis flos-aquae (Wittrock) Kirchner
Microcystis viridis (A. Braun) Lemmermann
Nodularia spumigena Mertens
Nostoc rivulare Kützing
Planktothrix agardhii (Gomont) Anagnostidis & KomÃirek
Schizothrix calcicola (C. Agardh) Gomont

Source: From Ref 17.

(e.g., boating, swimming) in contaminated freshwater bodies.[17] The odor of cyanobacteria blooms does not necessarily correlate to toxicity.[13] The production of odor-producing compounds (e.g., geosmin from blooms of *Anabaena circinalis* Rabenhorst) is variable;[18] therefore, odor from mass of cyanobacteria does not correlate to the formation of toxins.[10]

Hot weather encourages blooms and light winds concentrate the algae in slimy, blue-green masses near the shoreline. Blooms of cyanobacteria can form green, blue-green, milky-blue, red, or dark-brown scums. Treatment of water eliminates some of the toxins associated with cyanobacteria present in surface water. Although microcystin-LR and cylindrospermopsin in concentrations of 8 μg/L and 1.3 μg/L, respectively, occurred in Australian surface waters used for drinking water, analysis of the final drinking water detected only trace amounts (i.e., <1 μg/L) of these toxins.[19]

Food

Some nontoxic freshwater cyanobacteria (*Spirulina* spp., *Aphanizomenon flos-aquae* L. Ralfs ex Barnet et Flahault) are used as nutrient-rich food supplements (lipid, protein, chlorophyll, carotenoids, vitamins).[20] However, some health food products labeled as blue-green algae may also contain hepatotoxins (e.g., microcystin-LR) resulting from the contamination of these products by toxin-producing strains from the phylum Cyanobacteria. In a study of blue-green algae products harvested during a bloom of the microcystin-producing cyanobacteria, *Microcystis aeruginosa* forma *aeruginosa* Kützing microcystins were detected in 85 of 87 samples of blue-green algae products tested by enzyme-linked immunosorbent assay (ELISA) and high performance liquid chromatography (HPLC).[21] About 72% of the samples contained microcystins exceeding the provisional guideline of 1 μg/g. The most prominent microcystin was microcystin-LR. A Portuguese study of 12 samples of food supplements of *Aphanizomenon flos-aquae* from Internet distributors detected microcystins in all 12 samples as measured by molecular assays.[22] The concentration of microcystins ranged from 0.1 to 4.72 μg/g microcystin-LR equivalents. Decomposition of these toxins occurs with chlorination by sodium hypochlorite.[23] Analysis of blue-green algae and Spirulina food supplements from Canada, the United States, and Europe did not detect the presence of anatoxin-a or its transformation products as measured by HPLC/tandem mass spectometry.[24] The detection limits in this study ranged from about 0.5 to 1.5 pg.

TOXINS

Physiochemical Properties

Cyanobacteria produce a wide range of low and medium molecular weight metabolites that are primarily hepatotoxins (microcystins, nodularin, cylindrospermopsin), neurotoxins (anatoxin-a, anatoxin-a(s), homoanatoxin-a, saxitoxins), cytotoxins (cylindrospermopsin), or gastrointestinal irritants (aplysiatoxin, debromoaplysiatoxin, lyngbyatoxin).[10,11] These hepatotoxins and neurotoxins (i.e., low-molecular-weight anatoxins and saxitoxins) are secondary metabolites present only in certain species from the phylum Cyanobacteria. Cylindrospermopsin is a cyclic guanidine alkaloid that causes necrosis in various organs (e.g., liver) in animal models secondary to inhibition of protein synthesis.[25] Additionally, this toxin causes genotoxicity (DNA strand breakage, chromosome loss) in these animal models. Lipopolysaccharide endotoxins occur in the cell walls of all species from the phylum Cyanobacteria, and these compounds probably contribute to inflammation and gastrointestinal irritation associated with cyanobacteria. Other toxins isolated from freshwater cyanobacteria include aeruginopeptins, cyanopeptolins, and oscillamide.[26] Lyngbyatoxin A, aplysiatoxin, and debromoaplysiatoxin have been associated with the formation of local lesions. Figure 25.1 demonstrates the chemical structure of six important toxins isolated from

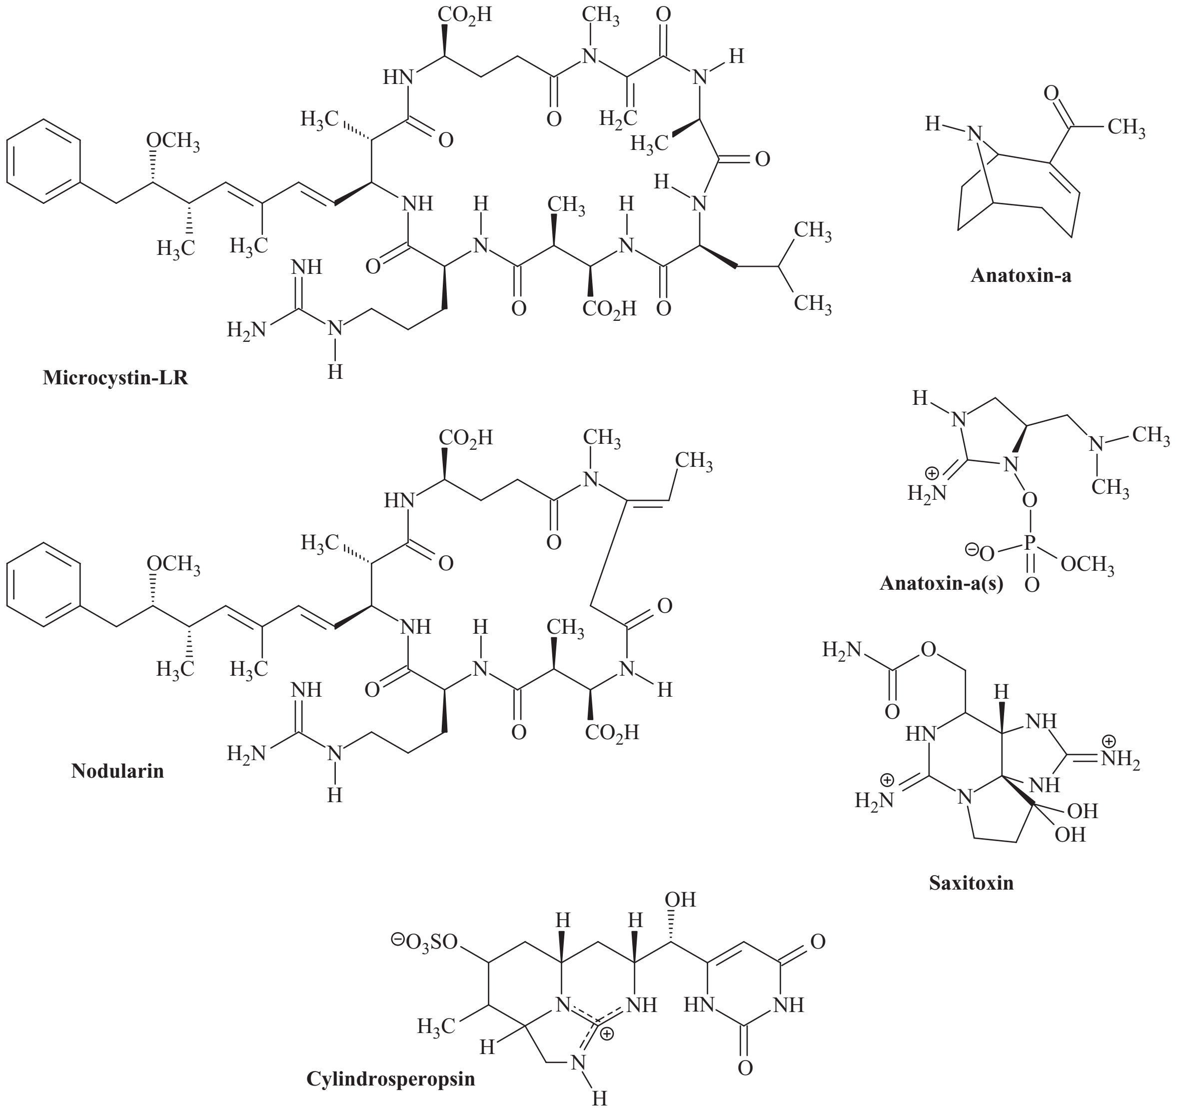

FIGURE 25.1. Structures of cyanobacteria toxins.

cyanobacteria. The blue pigment of cyanobacteria becomes apparent as the cells deteriorate and the edges of infected ponds become blue as these microorganisms desiccate. The presence of toxin-producing cyanobacteria in water does not necessarily imply a health hazard because the toxins are rapidly dispersed in water as long as the organisms remain widely dispersed.[13] The formation of dense mats and surface scum suggests that a health hazard may exist if substantial numbers of toxin-producing cyanobacteria are present.

There are over 70 variants of microcystin toxins that share a general structure containing three D-amino acids (alanine, β-linked *erythro*-β-methylaspartic acid, γ-linked glutamic acid), *N*-methyldehydroalanine, two variable L-amino acids, and a rare C20 β-amino acid [(3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid).].[27] The nomenclature for microcystin variants involves the methylation pattern based on the two variable L-amino acids. For example, microcystin-LR contains a leucine (L) and arginine (R) substitution at these sites. The synthesis of microcystin toxins occurs via a mixed polyketide synthase/nonribosomal peptide synthetase system called microcystin synthetase. The synthesis of microcystin in cyanobacteria involves an integrated polyketide-peptide biosynthetic pathway with unusual structural and enzymatic features, such as integrated *C*- and *N*-methyltransferases, *O*-methyltransferase, and the formation of β- and γ-carboxyl-peptide bonds.[28] The ribosomes are not part of the synthesis of microcystin. Detoxification pathways of microcystin include conjugation by the glutathione S-transferase system.[29]

Neurotoxins

Cyanobacteria produce at least 19 structurally related neurotoxic compounds including anatoxins, saxitoxin, neosaxitoxin, C-toxins, G-toxins, and LW (*Lyngbya wollei*)-toxins. Marine bacteria and marine dinoflagellates also produce saxitoxins that are commonly associated with shellfish poisonings. Anatoxin-a is a low-molecular-weight, bicyclic secondary amine isolated most commonly from *Anabaena flos-aquae* and *Anabaena circinalis* Rabenhorst. Other species from the phylum Cyanobacteria also produce anatoxin-a including species in the genera *Aphanizomenon, Cylindrospermum, Microcystis*, and *Plankothrix*.[12] This neurotoxin is a highly water-soluble compound that binds to nicotinic acetylcholine receptors to produce flaccid paralysis. Anatoxin-a is a potent nicotinic agonist that is sensitive to heat, light, and alkali.[30] The methylene homologue of anatoxin-a is homoanatoxin-a, which was isolated from *Planktothrix formosa*.[31] Homoanatoxin-a enhances acetylcholine release from peripheral cholinergic nerves as a result of the opening of voltage-dependent L-type calcium channels in neurons.[32] Despite similar names, anatoxin-a and anatoxin-a(s) are not structurally similar. Anatoxin-a(s) is a phosphate ester of cyclic *N*-hydroxyguanine that is the only natural organophosphate compound known.[33]

Hepatotoxins

Microcystins and nodularins belong to the okadaic acid class of protein phosphatase inhibitors. There are at least 80 microcystin variants and at least 5 nodularin variants as a result of amino acid substitutions and modification of the structure of these cyclic peptides. Microcystin toxins are heat-stable, cyclic heptapeptides predominately from hepatotoxin-producing species of the genus *Microcystis* that demonstrate tumor-promoting activity by the inhibition of protein phosphatases 1 and 2A.[34] These cyclic peptides have molecular weights between 900 and 1,100 daltons, and these compounds are stable in a wide range of pH. Microcystins contain two variable L-amino acids and the two following novel D-amino acids: *N*-methyldehydroalanine (Mdha) and 3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid (Adda). These toxins are named according to the variable L-amino acids (e.g., microcystin-LR contains leucine and arginine at the variable sites).

Dose Response

There is no correlation between the composition or density of a particular bloom and the concentration of toxins within the cyanobacteria.[3] The World Health Organization (WHO) adopted provisional guideline values of 20 µg microcystin-LR/L in recreational water and 1 µg microcystin-LR/L drinking water.[35] The National Health and Medial Research Council of Australia established a drinking water guideline of 1.3 µg microcystin-LR/L drinking water. Estimated guideline values for anatoxin-a and cylindrospermopsin based on animal testing were 12.24 µg/L water and 0.81 µg/L water, respectively.[10]

The lethality of microcystins varies at least 10-fold between different variants.[36] In studies of mice, the oral LD_{50} (5,000 µg/kg body weight) of microcystin-LR is approximately 100-fold lower than the intraperitoneal LD_{50} of the same compound.[37] The lowest observable effect level (LOAEL) in a study of pigs administered seven different congeners of microcystins (excluding microcystin-LR and microcystin-RR) was 280 µg MC-LR equivalents/kg body weight daily for 44 days.[38] The effects observed were limited to histological changes in the liver of these animals. At least 52 deaths from acute liver failure were attributed to the use of microcystin-contaminated dialysis fluid by renal dialysis patients in Brazil.[39] Based on postmortem liver concentrations of microcystins and exposure volumes, the estimated concentration of microcystin-LR equivalents in dialysis fluid was approximately 20-fold higher (19.5 µg/L) than the current WHO provisional guideline (1 µg/L) for drinking water. In rodent studies, anatoxin-a(s) binds to acetylcholinesterases in the blood. Based on this study, this compound is 10 times more toxic than anatoxin-a.[40]

Mechanism of Toxicity

Some species from the phylum Cyanobacteria contain lipopolysaccharide endotoxins that are released during decomposition, and most, but not all, serious risks to human health from cyanobacteria result from the production of hepatotoxins or neurotoxins. Microcystin toxins are potent hepatotoxins that inhibit several serine/threonine protein phosphatases including phosphatase types 1 and 2A. This inhibition causes disruption of normal cell metabolism and function, leading to intrahepatic hemorrhage and cell death. In rodent models, chronic administration of microcystin causes hepatocyte degeneration with necrosis, mononuclear leukocyte infiltration, and progressive fibrosis.[41]

The filamentous blue-green cyanobacterium, *Lyngbya majuscula* Harvey ex Gomont, produces lyngbyatoxin A as well as over 70 other toxins.[42] These toxins have contaminated meat from marine turtles, and consumption of this meat was associated with acute inflammatory changes of the gastrointestinal tract, intraoral lesions, weakness, headache, lightheadedness, and sali-

vation.[43] Contact with toxins from *Lyngbya majuscula* has also been associated with swimmer's dermatitis.[44,45]

Neurotoxins

A variety of freshwater species of *Anabaena, Aphanizomenon*, and *Oscillatoria* produce a nicotinic agonist (anatoxin-a) that binds irreversibly to the nicotinic acetylcholine receptor of the sodium channel of the postsynaptic neurotransmitter plate. In experimental animals, the action of this neurotoxin mimics acetylcholine and causes postsynaptic neuromuscular blockade and respiratory depression (fasciculations, muscle spasm, fatigue, and paralysis).[46,47] This potent acetylcholine receptor agonist essentially locks the sodium channel in the open position and produces overstimulation followed by paralysis. Strains of *Anabaena* species produce another neurotoxin unique to the phylum Cyanobacteria called anatoxin-a(s). This organophosphate compound causes a cholinergic-type syndrome by inhibiting acetylcholinesterase in a manner similar to synthetic organophosphate insecticides, but this unstable compound does not penetrate the blood–brain barrier.[1,48] Some species of *Anabaena* and *Aphanizomenon* also contain saxitoxin and neosaxitoxin. These two neurotoxins were first isolated from the marine algae (dinoflagellates) that produce "red tides" and cause outbreaks of paralytic shellfish poisoning. Saxitoxin blocks neuronal transmission and causes muscle paralysis by binding to the voltage-gated sodium channels in neurons.

Hepatotoxins

Hepatotoxins are the most common type of toxin formed by cyanobacteria. There are over 60 cyclic and ringed peptides produced by certain strains (e.g., *Microcystis, Nodularia*) from the phylum Cyanobacteria.[1] Microcystins are cyclic heptapeptide (seven amino acids), whereas nodularins contain five amino acids. Microcystins alter cellular structure by inhibiting protein phosphatases and disrupting the normal regulatory balance between phosphorylation and dephosphorylation. In experimental animals, these hepatotoxins are actively transported to the liver by the bile acid carrier transport system where these toxins produce liver damage and apoptosis. This damage includes lipid peroxidation, loss of membrane integrity, DNA fragmentation, hemorrhage, and massive centrilobular necrosis.[49,50]

CLINICAL RESPONSE

The symptoms associated with exposure to cyanobacteria are nonspecific (vomiting, diarrhea, malaise, rash, mucosal irritation).[51,52] Gastrointestinal illness associated with cyanobacteria in water supplies result either from the breakdown of a natural cyanobacterial bloom or the release of toxins from the lysis of cyanobacterial cells during the handling of bloom-associated water. Self-limited gastroenteritis (diarrhea, abdominal cramps, nausea, vomiting) occurs 3–5 hours after exposure to water containing certain species from the phylum Cyanobacteria.[17] Symptoms usually resolve within 1–2 days. Case reports associate local skin reactions (swelling, redness) and mucous membrane irritation (conjunctivitis, rhinitis) with exposure to cyanobacteria.[53,54] A few otherwise healthy individuals can develop a skin reaction to cyanobacteria during water recreational activities, but the rash is typically mild and resolves without treatment.[55] Contact with toxins from *L. majuscula* was associated with acute vesicular dermatitis similar to sunburn, but the rash appeared in the genital, perineum, and perianal areas.[44] Erythema and local pain occurred within several hours of contact followed by the formation of vesicles and desquamation. Despite the presence of neurotoxins (e.g., anatoxin-a) in some cyanobacteria, clinically significant neurological symptoms in humans to date have not been associated with exposure to cyanobacteria. A burning sensation in the mouth and throat, headache, myalgias, gastrointestinal symptoms developed 15–90 minutes after ingestion of seaweed contaminated with debromoaplysiatoxin and aplysiatoxin isolated from the red alga, *Gracilaria coronopifolia* J. Agardh.[56,57] Ingestion of seaweed contaminated by *L. majuscula* produced immediate burning sensation and an intraoral lesion that required up to 3 weeks to resolve.[58] Glycosidic macrolides (lyngbyaloside, lyngbyaloside B) isolated from *Lyngbya* species from the phylum Cyanobacteria are structurally similar to the polycavernosides associated with fatal seaweed poisoning from the ingestion of red alga.[59] Other fatal cases of seaweed poisoning have been associated with aplysiatoxin, which produces physiological effects similar to lyngbyatoxin A in animal models.[60] However, there are no well-documented human fatalities associated with the ingestion of cyanobacteria.

In a field study of Australian residents drinking water from a reservoir containing a heavy bloom of toxic *Microcystis aeruginosa*, consumption of contaminated water was associated with subclinical increase in the serum γ-glutamyl transpeptidase and alanine aminotransferase concentrations.[61] Increased fatalities from liver failure occurred in dialysis-dependent patients receiving treatment at a hemodialysis center where microcystins contaminated the water used for dialysis fluid.[62] Histological examination of liver tissue revealed disruption of liver plates, liver cell deformity, necrosis, cholestasis, cytoplasmic vacuolization, mixed leukocyte infiltration and multinucleated hepatocytes.[39]

The chronic effects of exposure to toxin-producing cyanobacteria are unclear. In animal studies, some of the hepatotoxins (e.g., microcystins) in certain cyanobacterial species are potent tumor promoters.[63] Although these toxins are potentially cofactors along with HIV and aflatoxins for the development of primary liver cancer, there is no direct evidence that these toxins produce tumors in humans.

DIAGNOSTIC TESTING

Analytical Methods

Light microscopy is the traditional method for monitoring water for cyanobacteria. Alternate methods for the detection of cyanobacteria in water columns include flow cytometry with autofluorescence/immunofluorescence and submersible spectrofluorometry with specificity for cyanobacterial pigments.[10] Limitations to the analysis of cyanobacterial toxins include the need for sample processing before analysis and the wide range of toxins (e.g., at least 80 variants of microcystins). Sample screening by mouse bioassay has been replaced by more sensitive and reliable assays (e.g., enzyme-linked immunosorbent assay, protein phosphatase assay).[64] Newer techniques for the detection, identification, and quantitation of cyanobacterial toxins include physicochemical methods (gas chromatography/mass spectrometry, high performance liquid chromatography [HPLC], HPLC/mass spectrometry with negative electrospray ionization),[65,66] biochemical techniques (protein phosphatase inhibition assay), and immunoassays (enzyme-linked immunosorbent assay [ELISA], fluorescent in situ hybridization, polymerase chain reaction [PCR]).[67,68] Covalent binding of microcystins to animal tissues limits the determination of microcystins to unbound microcystins unless special procedures (e.g., 2-methyl-3-methoxy-4-phenylbutyric acid oxidation) reduce tissue binding prior to analysis.[69] When stored at −70 °C (−94 °F), microcystins are relatively stable for at least 10 years.[65]

Currently, routine analysis of water samples for microcystin toxins involves sensitive biological screening procedures (e.g., antibody-based ELISA, protein phosphatase inhibition assays) followed by quantitation of the microcystin toxins by HPLC with photodiode array detection (PDA).[64] Solid-phase extraction with C_{18} silica or immunoaffinity columns enriches the concentration of microcystin toxins in environmental samples and helps eliminate contaminants. Most commercial tests analyze samples for the presence of cyanobacteria-related toxins (e.g., microcystins). By several orders of magnitude, polyclonal and monoclonal immunoassays are more sensitive for the detection of microcystin toxins compared with physicochemical methods, but these immunoassays did not detect the less toxic glucuronide conjugates or react with all the microcystins equally. Cross-reactivity of various microcystin and nodularin compounds as well as the occurrence of >70 variants of microcystin toxins limits the specificity of immunoassays for cyanobacterial toxins. Although constrained by the limited availability of purified standards for the hepatotoxins and neurotoxins, several physicochemical and biochemical methods complement the traditional mouse bioassay or immunoassays for the detection and confirmation of these toxins.[70] Liquid chromatography is the most widely available method for quantitation of microcystins and nodularins, primarily by reversed-phase C_{18} columns with UV detection. The use of gas chromatography with electron capture detection analyzes environment samples for anatoxin-a.[71] Analysis of samples by HPLC and ELISA are available to detect the presence of hepatotoxins (microcystin-LR, nodularins) in health food products. The use of photodiode-array HPLC with methanol extraction allows detection of microcystin concentrations as low as 250 ng/L.[72]

Biomarkers

Water

Current recommended guidelines for microcystin-LR equivalents and cylindrospermopsin in drinking water are 1 μg/L.[73] The amount of microcystin in algae blooms varies with water temperature, total phosphorus levels, and chlorophyll a concentrations. In a study of German recreational lakes, 26% of the lakes contained toxigenic cyanobacteria with the highest microcystin concentration in the waters outside scum areas ranging from 11–560 μg/L as measured by ELISA techniques.[74] The microcystin concentration in algae blooms changes during the seasons with water temperature. In a Chinese freshwater lake, the mean microcystin concentration varied between about 24 ± 4 μg/g dry algae and 97 ± 12 μg/g dry algae as measured by ELISA.[75] The highest microcystin concentrations occurred during high water temperatures, and the main microcystin was microcystin-LR. The concentration of cylindrospermopsin is relatively low compared with more dominant cyanobacterial toxins, such as microcystin-LR and anatoxin a.[76]

In the presence of species from the phylum Cyanobacteria, detection of chlorophyll-a concentrations exceeding 40 μg/L suggests that surface scums may form rapidly, particularly in large bodies of water subject to winds.[13] Severe scums are associated with chlorophyll-a concentration in open water samples exceeding 100–150 μg/mL. Toxic cyanobacteria blooms are unusual in

water containing total phosphorus concentration below 0.01–0.02 mg/L. The presence of phosphorus concentrations exceeding this concentration and chlorophyll-a concentrations >100 µg/mL suggest the potential for cyanobacteria blooms. In these situations, warnings against the recreational use of these waters are appropriate.

Humans

Microcystins are detectable in serum from dialysis patients for up to approximately 60–90 days after cessation of exposure to contaminated water. In a Brazilian study of 44 hemodialysis patients exposed to sublethal doses of microcystins in contaminated dialysis fluid, 90% of the initial serum samples contained detectable concentrations of microcystins as measured by ELISA.[77] Twelve of these patients were monitored for 57 days after the discovery of the contaminated water, and the total serum microcystin concentrations ranged from <0.16 ng/mL to 0.96 ng/mL following MMPB (2-methyl-3-methoxy-4-phenylbutyric acid) oxidation to release bound microcystins. Peak microcystin concentrations occurred about 1 month after exposure ceased.

TREATMENT

Treatment is supportive.

Chapter 26

PROTOZOA and INTESTINAL PARASITES

ENTAMOEBA HISTOLYTICA and AMEBIASIS

HISTORY

Molecular phylogeny places the genus *Entamoeba* on the lowermost branches of the eukaryotic tree near the genus *Dictyostelium*. Although this organism lacks mitochondria, *Entamoeba histolytica* possesses nuclear-encoded mitochondrial genes and remnant organelles.[1] Hippocrates first recognized amebiasis in a patient with fever and dysentery. In 1875, Fedor Losch isolated *E. histolytica* from a stool specimen of a patient with dysentery.[2] Leonard Rogers recommended emetine as the first effective treatment for amebiasis in 1912.[3]

EXPOSURE

Source

Entamoeba histolytica Schaudinn is the only pathogenic *Entamoeba* species, and humans are the primary reservoir of *E. histolytica*. Oral-fecal transmission is the main route of infection with the cyst spreading disease most commonly through contaminated water.[4] Some animal reservoirs of *E. histolytica* probably exist in dogs, monkeys, and pigs, but these sources are uncommon pathways for human infections.[5] Cockroaches and flies are potential but rare sources of the transmission of amebiasis to humans.[6] Male homosexuals and foreign travelers to developing countries are at the highest risk of acquiring amebiasis. In a study of recent symptomatic *E. histolytica* infections in large cities in Japan, amebiasis almost exclusively afflicted middle-aged men, probably as a result of exposure during homosexual activity and concomitant infection with HIV.[7]

PATHOGEN

Physiochemical Properties

Entamoeba histolytica cysts remain infective outside the host for weeks to months, particularly in damp conditions. However, low (<–5 °C/23 °F) and high (>40 °C/104 °F) temperatures destroy the cysts.

Mechanism of Toxicity

Within the intestinal lumen, ingested tetra-nucleate cysts of *E. histolytica* transform into trophozoites that disrupt the protective mucous layer overlying the mucosa of the colon, causing mucosal thickening and flask-shaped ulceration in the cecum and ascending colon.[8] The sigmoid colon and rectum rarely have lesions secondary to amebic infection.[6] These trophozoites excrete galactose and *N*-acetyl-D-galactosamine-specific lectin to adhere to colonic mucins. Subsequently, these trophozoites invade the large intestine, producing punc-

tate, yellowish white ulcers despite the lack of symptoms in many cases of infection.[9] The presence of proteolytic enzymes (collagenase, neutral proteases) and cysteine proteases facilitate the penetration of the trophozoites into the tissue. A study of the transcription of nearly 40,000 human genes in sections of human colonic xenografts obtained 4 hours and 24 hours following infection with *E. histolytica* demonstrated a relatively stereotypical response. This response involved increased expression of genes activated in cells undergoing stress and/or hypoxic responses, genes encoding cytokines, chemokines, and mediators in immune and inflammatory responses, and genes encoding proteins in response to tissue injury and repair.[10] Aggregation of amoeba in the mucin layer of the colon triggers encystation and the subsequent excretion of cysts in the stool that completes the life cycle of the amoeba.

Colitis occurs when the trophozoite penetrates the intestinal mucous layer, which is the main barrier to the intestinal invasion of the trophozoites. The lectin engages *N*-acetyl-D-galactosamine on *O*-linked cell-surface oligosaccharides on epithelial cells, neutrophils, macrophages, and T-lymphocytes of the host. Activation of human caspase 3, a distal effector molecule in the apoptotic pathway, results in rapid cell death and progression of the invasion of host tissue.

DOSE RESPONSE

The infective dose of *E. histolytica* cysts is low (i.e., <100) compared with bacterial causes of gastroenteritis.[11]

CLINICAL RESPONSE

Amebiasis causes both intraluminal and disseminated disease. Risk factors include recent foreign travel to or immigration from developing countries and homosexual contact. Despite widespread infection with *E. histolytica*, the vast majority of individuals with amebiasis remain asymptomatic or mildly symptomatic.[12] Determination of the prevalence of *E. histolytica* infections is complicated by the presence of a morphologically identical species (*Entamoeba dispar* Brumpt) that is nonpathogenic.

Colitis

The incubation period of *E. histolytica* is typically 1–4 weeks, but symptoms may develop months after ingestion of the cysts. The onset of symptoms of amebic colitis is insidious and variable with the clinical diagnosis of amebic colitis complicated by the lack of specific clinical features. Typically, amebic colitis presents with several weeks of crampy abdominal pain, watery or bloody diarrhea, and weight loss. Fever and bloody stools are not usually prominent features of amebic colitis. The differential diagnosis of the bloody diarrhea associated with amebic colitis includes bacterial gastroenteritis (*Shigella, Salmonella, Campylobacter*, enteroinvasive and enterohemorrhagic *Escherichia coli*), diverticulitis, ischemic colitis, inflammatory bowel disease, and arteriovenous malformation.

Complications

Complications of invasive amebiasis include liver abscess, toxic megacolon, pneumatosis coli (intramural air), acute necrotizing colitis, perianal ulcerations with fistula formation, and peritonitis. Rarely, a reactive collection of granulation and fibrous tissue (i.e., ameboma) proliferates in the lumen, causing pain and obstruction.

Amebic liver abscess is the most common extraintestinal manifestation of infection with *Entamoeba histolytica*.[13] Symptoms of right upper quadrant pain, fever, and cough typically develop within 2–4 weeks after the development of the liver abscess. Many patients with amebic abscess lack a history of intestinal disease within the preceding year.[14] Jaundice is an uncommon complication of amebic abscess unless the liver abscess is very large or multiple abscesses exist. Right-sided shoulder and chest pain may develop when the abscess involves the diaphragm. The abscess may rupture into the pleural space. Most pleuropulmonary amebiasis occurs in patients with amebic liver abscesses that extend into the pleural space. A pulmonary amebic lesion without either a liver abscess or amebic colitis is extremely rare.[15]

DIAGNOSTIC TESTING

Analytical Methods

Methods for the diagnosis of amebiasis involve microscopic examination of fresh or frozen stool and serological tests including the detection of *E. histolytica*-specific antigens or DNA in stool samples or the presence of anti-amebic antibodies in the serum.[1] The traditional technique for identification of trophozoites and cysts involves the microscopic examination of stained (Lugol's, D'Antoni's iodine) or unstained stool samples, but this method is relatively nonspecific because of the difficulty distinguishing *E. histolytica* from other nonpathogenic *Entamoeba* species (e.g., *E. dispar* Brumpt, *E. moshkovskii* Tshalaia). The presence of Charcot-Leyden crystals during stool examination indicates the presence of eosinophils in the intestinal lumen. Occasionally, the presence of ingested erythrocytes in trophozoites helps

distinguish *E. histolytica* from other *Entamoeba* species. Consequently, the diagnosis of *E. histolytica* requires confirmation with stool antigen or serum serology prior to initiation of treatment. The interpretation of serologic tests is complicated by the difficulty distinguishing current from past infections as a result of the persistence of positive serologic tests at least several years after infection. Serological tests are based on the presence of anti-galactose and *N*-acetyl-D-galactosamine-specific lectin IgG antibodies or the monoclonal anti-*E. histolytica* IgM antibodies. The former antibodies are detectable about 1 week after the onset of symptoms, whereas the latter usually develops during the first week of amebic colitis.[16] Antibody titers do not correlate well to the severity of the clinical manifestations of amebiasis or the response to therapy.[6] Recent DNA-based techniques include antigen detection methods and a single-step duplex polymerase chain reaction (PCR) procedure for rapid, specific, and sensitive identification of *Entamoeba histolytica*.[17] An Ethiopian study using PCR techniques suggests that some infections attributed to *E. histolytica* are mischaracterized because of the detection of non-pathogenic *E. dispar* using nonspecific techniques unable to distinguish between these two species.[18] The mischaracterization of *E. dispar* as *E. histolytica* results in unnecessary treatment with amoebicidal drugs, at least in some tropical and sub-Saharan countries.

Abnormalities

Colitis

During an acute infection with *E. histolytica*, the presence of Charcot-Leyden crystals, fecal erythrocytes, and the lack of fecal leukocytes are the most common laboratory findings. In a study of 289 Bangladeshi children (147 boys and 142 girls) between 2 and 5 years old followed for the development of diarrheal illness, visible blood or hemoccult-positive tests of stool samples occurred in 7% and 25%, respectively, of cases of *E. histolytica*-induced diarrhea.[19] Eosinophilia in the blood does not usually occur during amebic colitis.

Liver Abscess

Serum hepatic aminotransferase concentrations are usually normal or slightly elevated despite the presence of amebic liver abscess, but the serum alkaline phosphatase is usually normal. A mild to moderate leukocytosis along with anemia may occur in patients with amebic liver abscess. Ultrasonography and abdominal computed tomography are excellent imaging studies for the detection of liver abscesses, but the findings are nonspecific. A majority of patients with amebic liver abscess do not have detectable antigens in their stool.[1] Detection of serum amebic antigens and observation of trophozoites on liver biopsy/aspiration are the definitive diagnostic tests for amebic liver abscess.[20]

TREATMENT

Treatment of amebiasis includes the administration of both a luminal amebicide for cysts and a tissue amebicide for trophozoites. Common treatment of amebic liver abscess includes metronidazole (750 mg or 35–50 mg/kg every 8 hours for 7–10 days) or tinidazole (800 mg or 60 mg/kg 3 times daily for 5 days) and a luminal agent. Metronidazole is the drug of choice as a tissue amebicide. Administration of this antibiotic results in an 85–90% cure rate. Options for use of a luminal amebicide include iodoquinol [Yodoxin® (Glenwood, LLC, Englewood, NJ), 650 mg orally 3 times daily for 20 days], paromomycin (500 mg orally 3 times daily for 7 days), or diloxanide furoate (500 mg orally 3 times daily for 10 days). Dehydroemetine dihydrochloride is not currently used for amebiasis because of its cumulative skeletal and cardiac muscle toxicity.

Asymptomatic patients with confirmed *E. histolytica* infections should be treated with appropriate antimicrobial drugs. Treatment of *Entamoeba histolytica* infections depends on the presence of symptoms. For asymptomatic patients, appropriate antibiotic therapy includes paromomycin (25–35 mg/kg/day in 3 divided doses for 7 days) or diloxanide furoate (500 mg or 20 mg/kg orally 3 times daily for 10 days). Diarrhea is a common side effect of paromomycin; therefore, the treatment of symptomatic patients with paromomycin complicates the determination of whether persistence of diarrheal symptoms results from a continuing *E. histolytica* infection or from a side effect of paromomycin. The detection of *Entamoeba dispar* in stool samples requires no treatment.

CRYPTOSPORIDIUM PARVUM

HISTORY

Although Tyzzer identified *Cryptosporidium parvum* in the gastric glands of mice in 1905,[21] clinically significant infections in animals were not associated with this para-

site until 1955.[22] By 1971, this organism was a recognized cause of chronic diarrhea and debility in calves and by 1976 *C. parvum* was a recognized cause of acute gastroenteritis in humans.[23] In the 1980s, cryptosporidiosis was associated with chronic gastroenteritis in HIV-infected patients. This parasite is now associated with disease in at least 79 animal species worldwide, particularly in calves.[24]

EXPOSURE

Cryptosporidium is prevalent both in developed and developing countries. Of at least 10 valid species of *Cryptosporidium, C. parvum* is the most common pathogenic species in humans and in animals.[36] Common sources of *C. parvum* infections include moist environments, such as contaminated drinking water and swimming pools.[25,26] In rural areas of England, fecal pollution of water sources by livestock feces is the leading cause of human sporadic cryptosporidiosis.[27] The oocysts of this organism survive in ice, and contaminated ice can transmit cryptosporidiosis.[28] Infectious *Cryptosporidium* oocysts occur in the stools of immunologically compromised persons as well as sporadically in healthy individuals, Russian travelers, animal handlers, and homosexual men without AIDS.[29] This disease is highly contagious; therefore, person-to-person transmission is common.[30] Animal-to-human transmission occurs rarely.[31] Food is an uncommon source of infection by *C. parvum*.[32] The oocysts can survive for extended periods. The largest outbreaks of *C. parvum* infections result from the ingestion of contaminated municipal water supplies.[33]

PATHOGEN

Physiochemical Properties

Cryptosporidium is an obligate, intracellular, protozoan parasite that replicates in the host and excretes oocysts into the stool. Transmission occurs via the fecal-oral route. Oocysts remain infectious up to several months in moist environments, and the prolonged survival of oocysts at 4 °C (39 °F) in experimental conditions suggest that these oocysts could survive for prolonged periods of time in groundwater of countries with cold climates.[34] These organisms are relatively resistant to chlorine and pool filtration systems. In an experimental study, exposure to 80 ppm chlorine or to 80 ppm monochloramine produced 90% inactivation of *C. parvum* oocysts after 90 minutes.[35] These oocysts were 14 times more resistant to these agents compared with *Giardia* cysts. Although oocysts of *C. parvum* can remain viable for many months under favorable conditions, freezing and desiccation kills the oocysts.[36] Microwaving at full power for at least 20 seconds completely inactivates *Cryptosporidium* oocysts.[37]

Mechanism of Toxicity

Cryptosporidium parvum invades the mucosa of the proximal small intestine causing abnormalities of crypts including villous atrophy and crypt hyperplasia. Oocysts are minimally invasive because this pathogen colonizes the surface epithelial cells rather than the deeper layers of the intestinal mucosa.[38] An inflammatory infiltrate develops in the lamina propria and epithelium. These changes cause a secretory diarrhea by reducing absorption (decreased surface area) and increasing intestinal secretions (impaired epithelial enzymes).[39]

DOSE RESPONSE

The infective dose of *Cryptosporidium parvum* is relatively small (i.e., 10–100 oocysts).[40] In an experimental study of 29 healthy adults, the median infective dose was 132 oocysts as calculated by linear regression.[41] All 7 subjects developed evidence of *Cryptosporidium* infection after ingesting 1,000 oocysts. Of the 18 subjects who excreted *Cryptosporidium* oocysts, 11 subjects had one enteric symptom and 7 subjects had clinical signs of cryptosporidiosis (i.e., diarrhea plus one enteric symptom). Based on a hierarchical predictive population dose-response Bayesian assessment of *C. parvum*, a dose of 6×10^{-6} oocysts per exposure corresponds to 10^{-4} infections per capita year.[42] This endpoint does not account for secondary transmission of the infection among hosts. Using Monte Carlo simulation with the field survey data from the Sagami River watershed in Japan, reduction of the 95% confidence interval for risk of *C. parvum* infection below 10^{-4} requires one oocyte per 80 liters of drinking water.[43]

CLINICAL RESPONSE

Infections by *Cryptosporidium parvum* cause watery diarrhea that is usually benign in healthy patients. However, a chronic debilitating gastroenteritis may develop in immunocompromised patients (e.g., AIDS).[44] In a study of 68 otherwise healthy patients with cryptosporidiosis, the mean incubation period was about 7 days (range: 1–12 days) and the duration of illness was approximately 12 days (range: 2–26 days).[45] During an outbreak of cryptosporidiosis from the consumption of contaminated apple cider, the median incubation period was about 6 days (range: 10 hours to 13 days) and the median duration of illness was about 6 days (range: 1–16 days).[32] In an outbreak of cryptosporidiosis involving

285 confirmed cases, the most common symptoms were watery diarrhea (93%), abdominal cramps (84%), and vomiting (48%).[28] The clinical course of cryptosporidiosis in immunocompromised patients depends on host resistance (e.g., CD4 count); thus, the course ranges from transient infection to asymptomatic infection, chronic diarrhea, and fulminant infections. Humans with persistent cryptosporidiosis may develop hepatobiliary or pancreatic duct infections.[40]

Watery diarrhea (four bowel movements per day), weight loss ranging from 1–5 kg, and anorexia characterize the illness. Fever, chills, and vomiting appear uncommonly. Acute pancreatitis has been associated with infections by the *Cryptosporidium* parasite.[46]

DIAGNOSTIC TESTING

Analytical Methods

During an acute illness, the laboratory diagnosis of cryptosporidiosis usually involves the detection of oocysts in stool with acid-fast staining or modification of this staining process.[47] Most clinical laboratories do not routinely screen for *C. parvum*, and the laboratory should be notified of the necessity to screen the stool specimen for *C. parvum*. Detection may require analysis of implicated water and food. In patients with chronic diarrhea, identification of *C. parvum* as well as other intestinal coccidian infections (e.g., *Cyclospora cayetanensis, Isospora belli*) requires the use of special methods using the Kinyoun modified acid-fast stain.[48] More sensitive and specific detection methods (e.g., immunofluorescence assays, enzyme-linked immunoassays, DNA-based techniques) have been developed as an alternative to the time-consuming method of stool analysis for the detection of common intestinal parasites, such as *Entamoeba histolytica, Giardia lamblia*, and *Cryptosporidium parvum*.[49] The DNA-based (e.g., polymerase chain reaction [PCR]) techniques are important for the detection of clinically inapparent infection involving the excretion of small numbers of oocysts.[50]

Abnormalities

Endoscopic examination of the proximal small intestine is usually normal.[39] Examination of mucosal biopsies by light microscopy detects forms of *C. parvum* at the epithelial cell surface.

TREATMENT

Treatment of *C. parvum* infection primarily is supportive (fluid/electrolyte replacement, loperamide). In healthy patients, this self-limited, enteric illness usually resolves without therapeutic intervention. There is no antimicrobial agent that effectively eradicates cryptosporidiosis. Macrolide antibiotics (azithromycin, clarithromycin) demonstrate variable effectiveness against *C. parvum*.[40] Nitazoxanide, a nitrothiazolyl-salicylamide derivative, is active against *C. parvum* in animal models, and a clinical trial suggests that this antimicrobial agent reduces diarrhea in most patients with cryptosporidiosis within 3–4 days.[51] Feces from patients with cryptosporidiosis should be considered infectious.

CYCLOSPORA CAYETANENSIS

HISTORY

Although Eimer first identified *Cyclospora* in the intestines of moles in 1870, recognition of *Cyclospora* oocysts in humans did not occur until the late 1970s.[52] During the 1980s, case reports of diarrheal illness documented *C. cayetanensis* as a human pathogen in travelers from tropical countries (Mexico, Haiti, South Africa, India), in residents of Nepal and Peru, and in AIDS patients.[53] In some of these outbreaks, infection with *C. cayetanensis* occurred after the ingestion of drinking water despite the chlorination and filtration of the water supply.[54] Before 1995, most cases of cyclosporiasis in the United States occurred in travelers. The transmission of *Cyclospora* is unusual compared with other enteric diseases because freshly excreted cysts require several days to weeks outside the host to sporulate and to become infective.

EXPOSURE

Cyclosporiasis is widespread throughout tropical and subtropical regions with endemic infections reported in Nepal, Guatemala, Peru, and Haiti.[55] Although cyclosporiasis has marked seasonality, seasons associated with increased infective rates vary from one endemic region to another.[52] Although cyclosporiasis usually occurs in immunoincompetent patients (e.g., HIV/AIDS patients), gastrointestinal infections occur occasionally in immunocompetent patients,[56] primarily in foreign travelers and children.[57,58] The major source of cyclosporiasis is fecally contaminated fruits (raspberries)[59] and vegetables (lettuce, basil, snow peas),[60] but occasionally waterborne infections of *C. cayetanensis* occur.[61] Analy-

sis of samples of vegetables from foreign markets suggests that contamination by *Cyclospora* is substantially less than by *Cryptosporidium*. The contamination rate of *Cyclospora* and *Cryptosporidium* in market vegetables from an endemic area near Lima, Peru was <2% and 15–20%, respectively.[62] Simple washing of vegetables probably does not remove *Cyclospora*. Humans are the primary host for this species of *Cyclospora*, but other species (*C. talpae, C. caryolitica*) are present in the intestines of rodents and reptiles.[63] African primates are a reservoir for *C. cayetanensis*, but these primates probably are not a common source of human infections with this coccidian protozoan.[64] *Cyclospora* oocysts sporulate at temperatures of 25 °C–30 °C (77 °F–86 °F) in about 1–2 weeks, but temperatures <–20 °C (–4 °F) for 24 hours or 60 °C (140 °F) for 1 hour prevent sporulation.[65] Outbreaks of cyclosporiasis are not well documented in cooked or commercially frozen food.[52]

PATHOGEN

Physiochemical Properties

The genus Cyclospora is taxonomically similar to several other coccidian genera that cause human disease including Cryptosporidium, Isospora, Microspora, Nosema, Pleistophora, Microsporidium, Enterocytozon, Encephalitozoon, Trachypleistophora, Vittaforma, Sarcocystis, and Toxoplasma. The oocysts of *Cyclospora cayetanensis* are almost twice the size of *Cryptosporidium* oocysts. Extreme temperatures (e.g., pasteurization, commercial freezing) inactivate the former oocysts.[66]

Mechanism of Toxicity

Ingestion of sporulated oocysts of *C. cayetanensis* initiates an infection. In the small intestine, sporozoites invade the intestinal epithelial cells. This parasite is an intracellular human pathogen that causes inflammatory changes in the epithelium, mucosa, and lamina propria as well as villous atrophy and crypt hyperplasia. Sporulated oocysts are excreted in the stool; therefore, oral-fecal contact can transmit cyclosporiasis immediately.

DOSE RESPONSE

The attack rate for cyclosporiasis depends on the degree of immunity in the population as well as the number of oocysts. A pilot study of 7 healthy volunteers ingesting an inoculum of *Cyclospora* oocysts (approximately 200–49,000 oocysts) did not demonstrate gastrointestinal symptoms in the volunteers or oocysts in any stool samples during the 16-week observation period.[67] Person-to-person transmission is unlikely because the oocysts excreted in the stool are not sporulated.

CLINICAL RESPONSE

Characteristics of an infection by *Cyclospora* include a long incubation period and long duration of illness characterized by prolonged, relapsing diarrheal illness. The incubation period averages about 1 week with a range of 12 hours to 14 days, and disease patterns are typically seasonal depending on the locality.[52] The attack rates of cyclosporiasis are higher in adults than in children, and this disease is uncommon in children under 3 years of age.[53] Asymptomatic infections are common, particularly when *C. cayetanensis* is endemic. In healthy adults, cyclosporiasis is usually self-limited. Infection by *C. cayetanensis* usually produces prolonged, relapsing watery diarrhea, low-grade fever, nausea, and vomiting.[68] In a study of 180 Florida residents with laboratory-confirmed *Cyclospora* infections, the most common symptoms beside diarrhea were loss of appetite (92%), fatigue (91%), weight loss (90%), abdominal pain or cramps (70%), nausea (70%), fever (43%), and vomiting (30%).[69] Occasionally, a "flu-like" illness characterized by myalgias and arthralgias precedes the diarrhea. *Cyclospora* causes an opportunistic infection in HIV-seropositive patients associated with protracted, relapsing diarrhea and weight loss.[70] Complications of infections by *C. cayetanensis* include malabsorption syndrome, Guillain-Barré syndrome, acalculous cholecystitis in AIDS patients, and Reiter syndrome (ocular inflammation, sterile urethritis, and inflammatory arthritis).[71] Fatalities are rare.

DIAGNOSTIC TESTING

Analytical Methods

The laboratory diagnosis of cyclosporiasis depends primarily on the identification of oocysts in stool specimens, primarily by wet-mount phase-contrast microscopy of the 8- to 9-mm oocysts. Routine analysis of stool specimens for ova and parasites does not typically include the special techniques required to identify *Cyclospora cayetanensis* except the use of fluorescence microscopy to detect the natural autofluorescence of *Cyclospora* oocysts.[72] Consequently, the laboratory should be notified of the necessity to screen the stool specimen for *Cyclospora*. Identification of oocysts in the stool with wet preparations or modified acid-fast stain confirms the diagnosis of cyclosporiasis. Staining of *C. cayetanensis* with acid-fast techniques produces marked variability in color (light pink to deep red). The safranin procedure produces a uniform red to red-orange color

when modified by heat during the staining. Other methods of detecting *Cyclospora* infections include flow cytometry and quantitative real-time polymerase chain reaction (PCR) analysis and sporulation of oocysts in 2.5% potassium dichromate solution.[73,74] Detection may require analysis of implicated water and food. Methods of recovering *Cyclospora* oocysts from water samples are similar to the methods used to detect *Cryptosporidium* oocysts and *Giardia* cysts.

Abnormalities

Endoscopic examination of infected patients usually demonstrates mild erythema and friability of the mucosa in the small intestine.[75] Ulcers and hemorrhagic areas are not usually present.

TREATMENT

In addition to supportive care, chronic diarrhea associated with cyclosporiasis usually responds to a one-week course of trimethoprim-sulfamethoxazole (160 mg/800 mg or one double-strength tablet) twice daily, even in patients with HIV infection. Although ciprofloxacin (500 mg b.i.d.) is not as effective as trimethoprim-sulfamethoxazole, ciprofloxacin is an alternative antibiotic when patients cannot tolerate trimethoprim-sulfamethoxazole.[76]

GIARDIA LAMBLIA

HISTORY

Van Leeuwenhoek discovered *Giardia* in 1681 during observation of his own stool.[77] This flagellated, binucleated protozoan is a parasite of mammals, birds, reptiles, and rodents. *Giardia* is an ancient eukaryote that does not possess mitochondria. Vilem Lambl published the first line drawings of both the trophozoite and the cyst forms of *G. lamblia* in 1859.

EXPOSURE

Giardia lamblia Kofoid and Christiansen is one of the most common parasitic infections worldwide. The spread of giardiasis occurs primarily by oral-fecal contact with the cysts becoming immediately infective when passed in the stool.[78] Giardiasis occurs in every region of the United States, particularly in mountain areas.[79] Waterborne sources are the usual method of transmission because *G. lamblia* is relatively resistant to chlorination and survives easily in cold mountain streams. Person-to-person transmission of *G. lamblia* can occur in day care centers and institutions.

Source

Animal

Giardiasis is a zoonosis that allows cross-infectivity between animal reservoirs (rodents, dogs, cattle, beaver, big horn sheep). However, most human infections do not result from exposure to *G. lamblia* in animal reservoirs.[78] Oral-fecal transmission occurs between humans, particularly in the setting of poor sanitary conditions. Individuals at risk of developing giardiasis include travelers, backpackers (e.g., Rocky Mountains, Sierra Nevada, California coastal ranges), institutionalized individuals, diaper-aged children in day care, immunocompromised patients (HIV), homosexuals, and the elderly with a history of gastric surgery or with hypoalbuminemia.[80]

Food

Foodborne transmission of *Giardia* is rare, but food may be a source of giardiasis when fecal-contaminated food is inadequately cooked. Flies are a potential source of contaminated food as a result of acquisition of *Giardia* cysts from unhygienic sources.[81]

PATHOGEN

Physiochemical Properties

Cysts remain viable for up to 3 months in moist environments including streams and lakes. Ozone and ultraviolet light potentially deactivate *Giardia* cysts.[82]

Mechanism of Toxicity

Trophozoites develop in the stomach when the acid environment of stomach causes excystation of the ingested cysts. The trophozoites migrate to the duodenum and proximal jejunum where they attach to the epithelium and overlying mucus layers via a ventral adhesive disk. This parasite does not usually invade the mucosa and *G. lamblia* causes little or no mucosal inflammation of the small bowel.[83] Trophozoites encyst in the jejunum as a result of exposure to biliary secretions, and the cysts pass into the stool for dissemination.

DOSE RESPONSE

Ingestion of 10–25 cysts may produce giardiasis depending on the susceptibility of the patient.

CLINICAL RESPONSE

The incubation of giardiasis is about 1–2 weeks with a range up to about 1 month. In comparison with bacterial gastroenteritides, the onset of diarrhea is usually gradual and relatively mild, and the onset of illness occurs frequently with a feeling of intestinal uneasiness followed by nausea and anorexia.[84] The clinical manifestations of *Giardia* infections range from none to a chronic malabsorption-like syndrome. Transient lactase deficiencies may develop in symptomatic patients that persist a few weeks after treatment.[77] Although many infections with *Giardia lamblia* are asymptomatic, symptoms and signs associated with giardiasis include nausea, diarrhea, epigastric pain, steatorrhea, flatulence, anorexia, and weight loss.[85] Vomiting is unusual. Gastrointestinal symptoms resolve gradually over 2–4 weeks as a result of host defense mechanisms including the production of secretory IgA antibodies. Chronic *G. lamblia* infection may develop after acute symptoms resolve. The clinical features of subacute giardiasis resemble abdominal malabsorption syndrome with malaise, fatigue, bloating, crampy abdominal pain, excessive flatus, steatorrhea, weight loss, loose stool, abdominal distension, and foul-smelling stools. The persistence of diarrhea beyond 2 weeks is consistent with giardiasis. Rarely, a reactive arthritis of the lower extremities, rash, and urticaria may complicate giardiasis.[86]

DIAGNOSTIC TESTING

Analytical Methods

Giardia lamblia is a pear-shaped, binucleated, flagellated protozoan. The diagnosis of giardiasis traditionally depended on the direct detection of trophozoites or cysts in stool samples. Trophozoites occur primarily in diarrheal stools whereas cysts appear in both formed and loose stools of infected cases. Examination of three stool specimens in infected patients increases the sensitivity of stool analysis for *G. lamblia* to 85–90%.[87] More sensitive, rapid, and specific detection methods (e.g., immunofluorescence assays, enzyme-linked immunoassays, DNA-based techniques) have been developed in recent years as an alternative to the time-consuming method of stool analysis for the detection of common intestinal parasites, such as *Entamoeba histolytica, Giardia lamblia*, and *Cryptosporidium parvum*.[49,88,89] Duodenal biopsy is highly sensitive option when the clinical presentation is highly suspicious of giardiasis and stool examinations are negative, but invasive procedures are not usually necessary for diagnosis. Duodenal aspiration is a less sensitive method for the detection of giardiasis than duodenal biopsy.[90]

Abnormalities

Eosinophilia, leukocytosis, and fecal leukocytes are not associated with giardiasis because the trophozoites do not invade the intestinal mucosa.

TREATMENT

Since the discontinuation of quinacrine production in 1992, metronidazole (250 mg every 8 hours for 5–7 days) has been the drug of choice for the treatment of giardiasis. Paromomycin (500 mg 3 times a day or 5–10 days) is an alternative for pregnant women afflicted with giardiasis, particularly during the first trimester. Tinidazole has a high cure rate (90–98%) in an easy to use dosage (2 g in adults), but this drug is not available in the United States. Furazolidone is an effective alternative to metronidazole, but this drug requires administration 4 times a day for 7–10 days.[91] Nitazoxanide (Romark Laboratories, Tampa, FL) has been approved by the US Food and Drug Administration (FDA) for the treatment of diarrhea caused by *Giardia* in children aged 1–11 years. The treatment of asymptomatic patients with giardiasis is controversial because of the high reinfection rate.

Chapter 27

GASTROINTESTINAL VIRUSES

HISTORY

Because of the difficulty identifying viruses, these organisms were not suspected causes of gastroenteritis until the 1940s.[1] In 1972, Kapikian et al isolated the first gastrointestinal virus (Norwalk virus) from a stool sample during an outbreak of infectious, nonbacterial diarrhea.[2] Soon afterward, several other viruses were identified in the stools of children with infectious diarrhea including rotavirus,[3] astrovirus,[4] and enteric adenovirus.[5] Subsequently, other viruses associated with infectious gastroenteritis included picobirnavirus, coronavirus, pestivirus, and torovirus. Rotavirus was identified as the leading cause of acute gastroenteritis in young children, and this illness is a major cause of morbidity and mortality in children under 3 years of age worldwide.[6] In 1998, a rhesus-based tetravalent rotavirus vaccine (Rotashield®, Wyeth Pharmaceuticals, Madison, NJ) was approved in the United States for the routine vaccination of infants with three doses at ages 2, 4, and 6 months. However, this vaccine was withdrawn from the US market within one year because of the association of the vaccine with an increased incidence of intussusception, particularly during the first 3–14 days after the first dose.[7] Subsequently, a monovalent vaccine based on an attenuated human rotavirus strain (P1A[8]G1) was developed by the Belgian firm, GSK Biologicals (in US, GlaxoSmithKline, Philadelphia, PA), and this vaccine is licensed in at least 30 countries for the prevention of severe rotavirus gastroenteritis.[8] In 2006, a live, oral, human-bovine reassortant rotavirus vaccine (Rotateq®, Merck & Co., Whitehouse Station, NJ) was approved for use in the United States. This pentavalent vaccine currently is recommended for initiation in infants between 6 and 12 weeks of age.[9] Preclinical trials on this pentavalent vaccine did not detect an increased incidence of intussusception in infants <8 months of age when compared with infants not receiving the vaccine.[10]

EXPOSURE

Taxonomy and Classification

Rotaviruses (Reoviridae)

Rotaviruses have a wheel-like shape characterized by a non-enveloped, 70-nm icosahedral structure. The double-layered capsid is composed of an outer capsid (VP7 and VP4 proteins) and an inner capsid (primarily V6) surrounding the genome-containing core (VP1-VP3).[11] The genome contains 11 segments of double-stranded RNA that encode these six structural VP proteins [VP1, VP2, VP3, VP4 (VP5 + VP8), VP6, VP7] and six nonstructural proteins (NSP1-NSP6).[12] Figure 27.1 displays the structure of a rotavirus. The virulence of rotaviruses is likely related to NSP4, which is probably an enterotoxin that causes diarrhea in experimental animals.[13] Rotaviruses are classified into at least seven groups (A–G) and two subgroups (I, II) based on the antigenic properties of the VP6 protein in the inner capsid. Human gastroenteritis is associated with groups A, B, and C.[14] Serotyping is based on the antigenic differences in the two following proteins in the outer capsid: VP7 glycoprotein (G-type) and VP4 protease

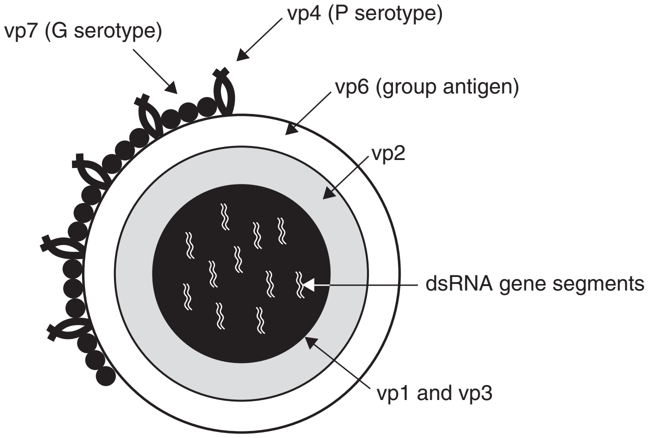

FIGURE 27.1. Structure of rotavirus. Adapted from Zahn M, et al. Clinical and epidemiological aspects of rotavirus infection. Pediatr Ann 2006;35:24.

(P-type). Because the two gene segments for VP7 and VP4 segregate independently, the typing system involves both G and P types. The characterization of P types by traditional methods is difficult; therefore, molecular methods are used to define genotype based on sequence analysis. These genotypes correlate well to serotypes, and these genotypes are placed in brackets. The most prevalent serotypes of rotavirus in the United States include P1A[8]G1, P1B[4]G2, P1A[8]G3, P1A[8]G4, P1A[8]G9, and P2A[6]G9.[15]

Enteric Adenoviruses (Adenoviridae)

Most enteric adenoviruses associated with gastroenteritis are 70-nm, nonenveloped viruses with an icosahedral structure. There are at least eight proteins in the core that maintain the integrity of the genome, which consists of a linear molecule of double-stranded DNA.[16] The most common serotypes involved with gastroenteritis belong to subgenus F (serotype 40, 41) and, rarely, to subgenus A (serotypes 12,18,32) and subgenus C (serotypes 1,2,5,6).[14]

Astroviruses (Astroviridae)

Under electron microscopy and physiological pH, these viruses have an icosahedral structure with obvious spikes and a diameter of 41 nm. In alkaline pH, astroviruses are small (28 nm) round organisms with the appearance of a five- or six-pointed star. The genome consists of single-stranded RNA with three open frames (ORFs). These ORFs encode a viral protease (ORF1a), viral polymerase (ORF1b), and a protein capsid precursor (ORF2). Serotyping is based on the immunoreactivity of capsid proteins (VP26) or the nucleotide sequence of a 348-bp region of the ORF2. There are at least eight serotypes (HAstV 1–8) with serotype 1 being the most common serotype associated with gastroenteritis.[17]

Caliciviruses (Caliciviridae)

The two genera of caliciviruses associated with gastroenteritis are *Norovirus* (Bristol virus, Desert Storm virus, Hawaii virus, Jena virus, Norwalk virus, Snow Mountain agent, Southampton virus, Toronto virus) and *Sapovirus* (London virus, Parkville virus, Sapporo virus). These viruses contain a single structural capsid protein with icosahedral symmetry that forms a continuous shell with arch-like protrusions. There are 32 cup-shaped depressions on the axes of the icosahedron that are characteristic of these viruses. The genome contains single-stranded RNA organized into three ORFs, which encode RNA-dependent RNA polymerase and helicase (ORF1) and a structural protein for the capsid (ORF2).[14] There are at least five norovirus genogroups (GI-GV), which contain at least 31 genetic clusters. GI, GII, and GIV strains infect humans, whereas GIII and GV strains infect cattle and mice, respectively.[18]

Torovirus and Coronavirus (Coronaviridae)

Toroviruses are enveloped, 100–140 nm viruses with a helicoidal symmetry to the capsid. The genome contains single-stranded RNA. Coronavirus are relatively large (60–220 nm) RNA viruses with helicoidal symmetry and a spiculated envelope. The role of coronaviruses in viral gastroenteritis is not well defined.[19]

Picobirnavirus

These small (30–40 nm), nonenveloped RNA viruses have a capsid with icosahedral symmetry. The genome is bi- or tri—segmented, double-stranded RNA.[20]

Source

The two classic types of viral gastroenteritis are epidemic and sporadic with the most common agents for these two types of gastroenteritides being 27-nm noroviruses and 70-nm group A rotaviruses, respectively.[21] Noroviruses are highly contagious organisms that cause epidemics of gastrointestinal illness in older children and adults, primarily genogroups GI and GII.[22] Rotavirus is the major cause of sporadic, viral gastroenteritis in young children primarily during the winter months, and there are five major serotypes (G1-G4, G9) with other serotypes (G12) occasionally involved.[23] The

actual serotype involved with rotavirus-induced gastroenteritis varies with season and geography.[24] Group A rotaviruses sometimes cause epidemics of adult gastroenteritis in nursing homes, schools, and other institutions.[25] Other viral sources of sporadic gastroenteritis include enteric adenoviruses type 40 and 41, astrovirus, and sapovirus.[26] Adenovirus type 40 is prevalent year-round, whereas adenovirus 41 infections occur primarily in late autumn.[27]

Environment

The major route of transmission of the noroviruses is the fecal-oral route, primarily by direct person-to-person contact or the consumption of fecally contaminated food or water. Occasionally, both person-to-person and foodborne transmission of multiple strains of norovirus may cause an outbreak of gastroenteritis.[28] Although aerosolization of vomitus contaminated by noroviruses can cause infection, there is little evidence that transmission of noroviruses occurs by inhalation. Fomite contamination is also a source of norovirus infection. Viral shedding usually appears with the onset of symptoms and continues up to at least 5 days after illness begins. Occasionally, noroviruses can be recovered in stool samples collected 2 weeks after recovery. Community waterborne outbreaks of norovirus disease typically result from the contamination of private wells or recreational waters by sewage.[29] Transmission of rotaviruses also occurs by the fecal-oral route from close person-to-person contact or fomites.[30] Asymptomatic infants are a common source of rotavirus as a result of the high concentrations (i.e., 10^{12} viruses/g) of rotaviruses excreted in the stool.[31] By the age of 3 years, most (i.e., 90%) children in both developed and developing countries have antibodies against rotaviruses.[21] Hygienic measures have limited effect on the transmission of rotavirus infections, and this virus is an important cause of childhood gastroenteritis in both developed and developing countries.[32]

Animal

Although animal rotaviruses are probably not a significant reservoir for human disease, fecal samples from primates, cows, pigs, and rodents may contain Group B rotaviruses.[33] These animal rotavirus strains possess a high degree of genetic homology with human strains, but animal-to-human transmission is uncommon because *most* animal rotaviruses are species specific.[34] Human toroviruses associated with gastroenteritis in immunocompromised patients serologically resembles bovine (Breda virus)[35] and equine (Berne virus)[36] toroviruses. There are no known animal reservoirs of noroviruses, but waterborne sources of the disease occur frequently as a result of contamination by sewage. Picobirnavirus is widespread in both humans and animals (e.g., chickens).[20,37] Sapovirus does not have a known animal reservoir, and transmission presumably occurs by fecal-oral route, primarily in children.[38]

Food

The epidemic form of viral gastroenteritis affects institutions, communities, families, cruise ships, camps, and schools, primarily by noroviruses genogroups GII and, to a lesser extent, GI.[39,40] Noroviruses cause a majority of the cases of foodborne gastroenteritis in the United States.[41] Foodborne sources of gastrointestinal illness associated with noroviruses include cake frosting, drinking water, orange juice, salads, fresh produce, sandwiches, lettuce, and European oysters.[27,42,43] Waterborne outbreaks of norovirus-induced gastroenteritis usually occur as a result of the contamination of well water and, to a lesser extent, surface water by sewage.[44] Molluscan shellfish (oysters, mussels) are filter-feeders that accumulate environmentally stable, positive-stranded RNA viruses, such as norovirus.[45,46] Noroviruses are resistant to sewage treatment and high concentrations of these viruses occur in water contaminated by sewage, particularly during the epidemic season. The primary pathogens associated with shellfish-borne gastroenteritis are noroviruses, which bind specifically to digestive ducts by carbohydrate structures with a terminal *N*-acetylgalactosamine residue in an α-linkage.[47] Following exposure, oysters become rapidly contaminated, and natural depuration of the viruses from oysters is slow (i.e., several weeks). In an *in vivo* study of oysters contaminated with norovirus, the depuration of norovirus over 48 hours was minimal (7%) compared with the natural removal of bacteria (95%).[48] Most foodborne outbreaks of norovirus-induced illness result from direct contamination of food by a food handler immediately prior to consumption. Outbreaks of rotavirus gastroenteritis typically occur at day care centers, preschools, and other locations where there are large numbers of children under 5 years of age. Occasionally, outbreaks of rotavirus infections develop in adults (e.g., nursing homes), where fecal contamination of food (e.g., salad vegetables) occurs.[49]

Food Processing

Cooking does not necessarily destroy norovirus-contaminated food, including the cooking of raw oysters.[50] Temperatures above 60 °C (140 °F) are necessary to inactive noroviruses.

PATHOGEN

Physiochemical Properties

Both noroviruses and rotaviruses are stable in most typical environmental conditions. Noroviruses are relatively resistant to sodium hypochlorite (<300 ppm), 70% ethanol, and alteration in pH.[51] Freezing does not kill noroviruses, and gastrointestinal illness can occur after consumption of frozen oysters contaminated with noroviruses.[52] The ability of noroviruses to survive high concentrations of chlorine (<10 mg/L for <30 minutes) and temperatures from freezing to 60 °C (140 °F) facilitates the spread of these viruses in recreation and drinking water.[53] Rotavirus is relatively resistant to glutaraldehyde, iodine, and hexachlorophene, whereas calcium chelators and high concentrations of ethanol or chlorine are required to inactivate rotavirus.[54,55]

Mechanism of Toxicity

The mechanism of toxicity associated with viral gastroenteritis is not well defined because of the difficulty culturing these viruses *in vitro*. However, current evidence indicates that the etiology of the diarrhea associated with viral gastroenteritis is multifactorial. The enterocytes lining the small intestine are divided into crypt cells and mature enterocytes with the latter being differentiated by digestive and absorptive functions. Pathologically, rotaviruses infect mature enterocytes in the distal tips of the villi in the proximal two thirds of the ileum.[56] Trypsin-like proteases cleave VP4 and activate rotavirus. Animal studies indicate that multiplication of rotavirus particles in these mature enterocytes causes apoptosis, increased epithelial cell turnover, and a shutoff of gene expression in enterocytes showing viral replication.[57] The villous cells are primarily absorptive, whereas the crypt cells are secretory. Consequently, atrophy of the epithelium of these villi results in a net enhancement of secretion because of the imbalance between absorption of fluid by the enterocytes and the secretion by the crypt cells. Beside the malabsorption mechanism, other contributory mechanisms include reduced permeability to macromolecules (e.g., lactulose) and stimulation of the enteric nervous system with subsequent enhancement of intestinal fluid and electrolyte secretion by the rotavirus enterotoxin, NSP4.[58]

DOSE RESPONSE

There is substantial variation between different strains and between individuals receiving the same viral inoculum.[59] The infection rate and severity of illness depends on the type of virus (e.g., norovirus produce high frequency of symptoms), the virulence of the strain (e.g., rotavirus serotypes G2 and G3 produce more serious illness), the size of the inoculum, individual immunity, and the general health of the patient. The infectious dose of noroviruses is low with the ingestion of as few as 10–100 viral particles of norovirus causing gastrointestinal illness.[60] In a study of 59 healthy volunteers ingesting 30 mL of a 1:600 dilution of the 8F IIa strain of Norwalk agent, 34 (57%) subjects developed a gastrointestinal illness.[61] An additional 8 developed serum antibodies to noroviruses, but they remained asymptomatic. Seventeen (29%) of these volunteers did not develop any gastrointestinal symptoms and they remained seronegative to noroviruses.

CLINICAL RESPONSE

Adults

Epidemic viral gastroenteritis is typically a self-limited, mild gastrointestinal illness characterized by nausea, vomiting, non-bloody diarrhea, abdominal discomfort, malaise, anorexia, headache, and low-grade fever. Dehydration and electrolyte imbalance are the most serious complications of viral gastroenteritis. The mean incubation period for noroviruses involved in epidemic viral gastroenteritis is typically approximately 24–36 hours with a range of 10 to 61 hours.[21,28] The duration of illness typically ranges from 12–60 hours with vomiting occurring in over 50% of the cases, particularly in children.[62] Nonspecific symptoms (e.g., myalgias, fever, chills, headache) often develop during the illness. Immunity to noroviruses typically lasts 4–6 months, but re-infection after that period usually causes less severe illness. Long-term sequelae of norovirus-induced illnesses do not usually occur. In an outbreak of foodborne gastroenteritis caused by group A rotavirus, the median duration of illness was 4 days with a range of 1 to 8 days.[25] Rotavirus-induced gastroenteritis in adults typically occurs in travelers to developing countries, persons caring for children with rotavirus gastroenteritis, immunosuppressed patients, and the elderly.[63] Symptomatic astrovirus infections also occur in the elderly with infections rarely occurring in healthy adults.[64]

Children

The sporadic form of viral gastroenteritis typically involves the development of rotavirus-induced vomiting and diarrhea in infants and young children <2 years old.[65] In unvaccinated populations, group A rotavirus is the most common cause of severe gastroenteritis in child under 5 years of age.[66] In a Venezuelan study of

mortality in children from diarrhea, rotavirus was the leading cause of death (21 of 100 cases).[67] Group B and group C rotavirus are less common causes of childhood gastroenteritis than group A rotavirus. Almost all children develop rotavirus infections by the age of 5 years, but the severe form of this illness usually occurs in children aged 3–36 months. Infection by rotavirus during the neonatal period is usually asymptomatic, probably as a result of the persistence of maternal antibodies. Additionally, up to about one-half of rotavirus infections during the first 2 years of life are asymptomatic.[68] Most cases of rotavirus-related gastroenteritis in temperate climates occur between October to April with US outbreaks beginning in the late autumn in the Southwest and ending early in the next calendar year in the Northeast.[69] The clinical course is highly variable ranging from subclinical infection to severe diarrhea and dehydration.[70] The clinical course of rotavirus-induced gastroenteritis is typically more severe than other viral gastroenteritides (adenovirus, astrovirus, calicivirus).[14] The incubation period for rotavirus-induced gastroenteritis is about 24–48 hours. The illness frequently begins abruptly with vomiting preceding diarrhea, which often has a characteristic smell.[70,71] The diarrhea may be explosive, numbering up to 10–20 stools during the severe phase of the illness. In some cases, diarrhea does not develop during rotavirus-induced gastroenteritis.[11] High temperatures (>102 °F/39 °C) can accompany the illness. Symptoms typically resolve in 3–7 days. Although vomiting and fever are more common in rotavirus-induced gastroenteritis than in norovirus-induced illness, there is no constellation of presenting symptoms that separates these two major causes of viral gastroenteritis.[72] Immunity after infection often is incomplete, but subsequent infections are usually less severe than the original infection.[73] Viremia can occur during viral gastroenteritis. Rarely, case reports associate extraintestinal infections (e.g., encephalitis, respiratory infections, poliomyelitis-like syndrome) with rotavirus or norovirus infections in children.[74–76] Although administration of the tetravalent rhesus-human rotavirus vaccine was associated with an increased incidence of intussusception, a retrospective study of 124 cases of intussusception and 450 cases of rotavirus found no clear evidence of an epidemiological association between rotavirus and intussusception.[77] Several case series associate the outbreak of hemorrhagic gastroenteritis and necrotizing enterocolitis with rotavirus infection both in neonates and in infants.[78,79] Astroviruses (i.e., predominately serotype 1) are the second most common cause of hospitalization for viral gastroenteritis in children during the first 2 years of life.[80] The incidence of astrovirus gastroenteritis is highest during the winter, similar to rotavirus.[81]

Immunosuppressed Patients

The main cause of severe viral gastroenteritis in immunosuppressed patients (AIDS, transplant recipients) are cytomegalovirus and Epstein-Barr virus.[14] When compared with rotavirus and astrovirus infections, torovirus is more often associated with persistent diarrhea and nosocomial infections in children, particularly in immunosuppressed children.[82] Additionally, bloody diarrhea is more common in torovirus-infected patients compared with children infected by rotaviruses or astroviruses. Picobirnavirus appears in fecal specimens collected from HIV-infected and noninfected patients with gastrointestinal symptoms in several countries, and some studies suggest that these viruses cause gastroenteritis in immunocompromised patients.[83]

DIAGNOSTIC TESTING

Analytical Methods

Clinically, viral gastroenteritis is a diagnosis of exclusion based on the clinical presentation and a history of an epidemic. Confirmation of viral gastroenteritis traditionally involved direct visualization of the virus by electron microscopy in a reference laboratory. The limit of detection of electron microscope for rotavirus or norovirus particles is about 10^6–10^7 viral particles/mL stool.[84] Detection of viral infections by electron microscopy requires refrigeration of the sample rather than freezing, which destroys the morphology of the viruses. Clinical specimens must be transported in sealed, insulated, waterproof containers on ice or frozen refrigerant packs. Virus particles are detectable in these refrigerated samples for about 2–3 weeks. Immune electron microscopy improves the sensitivity of electron microscopy by 10- to 100-fold.[60] Cell culture is a slow, difficult technique, particularly for human torovirus, coronavirus, and calicivirus.[85,86] The difficulty culturing noroviruses in cell cultures and laboratory animals limits the detection of these organisms in bioassays. The most important methods for the detection of viral gastroenteritis are molecular biology techniques and immunoassay using monoclonal or polyclonal antibodies. Currently, commercial tests for group A rotavirus, adenovirus, and astrovirus are available based on agglutination with latex particles, enzyme immunoassay (EIA) technology, and immunochromatography. In general, EIA techniques are highly specific and more sensitive (i.e., 10^4–10^6 viral particles/mL) for the detection of viruses than visualization by electron microscopy, particularly for the detection of group A rotavirus, group C rotavirus, adenovirus, and astrovirus using monoclonal antibodies.[87,88] The detection of recent infection involves seroconver-

sion as defined by a ≥4-fold rise in IgG antibody titer between the acute phase serum sample (within 5 days of onset of illness) and the convalescent phase (3–6 weeks after illness begins). A simple rapid, enzyme-linked immunosorbent assay (ELISA) is available to detect rotavirus as a cause of diarrheal epidemics. Reverse transcriptase-polymerase chain reaction (RT-PCR) techniques are more sensitive (10^2–10^4 viral particles/mL) than immunoassays,[89] and PCR is useful to confirm positive results from immunoassay methods.[14] Rotaviruses are detectable by RT-PCR with type-specific primers for gentotypes G and P.[90]

Currently, the most sensitive analytical technique for the detection of noroviruses in stool, vomitus, and environmental swabs is the use of a RT-PCR-oligoprobe.[91] The detection limit of noroviruses using this method is >100-fold lower than radioimmunoassay. The optimum time for the detection of noroviruses in stool samples is 48–72 after the onset of symptoms. However, viral shedding continues beyond this period in most cases of rotavirus gastroenteritis, depending in part on the severity of the illness. In a study of 37 children hospitalized with rotavirus gastroenteritis, rotavirus was detectable by immunoassay and RT-PCR for 4–57 days with viral shedding ceasing in 43% (16) of the cases within 10 days of the onset of diarrhea.[92] A real-time RT-PCR method is available for the detection of astroviruses with relatively high sensitivity (0.0026 IU/μL) compared with conventional RT-PCR.[93]

Biomarkers

Rotavirus antigens are detectable in the serum of patients for about 3–7 days after the onset of illness as measured by enzyme immunoabsorbent assay, but most confirmatory studies for viral gastroenteritis usually involve the identification of viruses in fecal samples.[94]

Abnormalities

Fecal leukocytes and erythrocytes rarely occur in typical cases of viral gastroenteritis with the exception of human torovirus infections in immunosuppressed patients. Otherwise, the most common laboratory abnormalities are the electrolyte changes associated with dehydration.

TREATMENT

Treatment is supportive. Every child should be evaluated for signs of dehydration based on an assessment of urine output, clinical history of vomiting and diarrhea (frequency quantity, content), weight loss, physical findings (heart rate, blood pressure, respiratory rate, skin turgor, capillary refill, mucous membrane moisture, sunken eyes, mentation), and laboratory analysis (urine specific gravity, serum electrolytes). Table 27.1 displays the assessment of the degree of dehydration based on clinical and laboratory examinations. Oral administration of glucose-electrolyte solutions helps replace fluid and electrolyte losses. The current recommendation by the World Health Organization (WHO, Geneva, Switzerland) for oral rehydration solution is 75 mmol sodium/L, 20 mmol potassium/L, 65 mmol chloride/L, 30 mmol base/L, and 75 mmol glucose/L. Small, frequent feedings may be necessary when vomiting persists. The early introduction of age-appropriate foods helps reduce stool volume. Foods containing complex carbohydrates (rice, potatoes, bread, wheat, cereals) yogurt, fruits, lean meats, and vegetables are preferable to fatty food or

TABLE 27.1. Assessment of Degree of Dehydration

Symptom	Minimal or No Dehydration (<3%)*	Mile to Moderate Dehydration (3–9%)*	Severe Dehydration (>9%)*
Mental status	Alert, active	Normal to fatigued, restless, or irritable	Lethargic, apathetic, obtunded
Thirst	Drinks normally, may refuse liquids	Thirsty	Drinks poorly
Heart rate	Normal	Normal to increased	Tachycardia unless pre-terminal
Pulse Amplitude	Normal	Normal to decreased	Weak to absent
Breathing	Normal	Normal to tachypneic	Variable
Eyes	Normal	Slightly sunken	Deeply sunken
Tears	Good tearing	Decreased	Absent
Mouth/tongue	Moist	Dry	Parched
Skin fold	Instant recoil	Recoil <2 seconds	Recoil >2 seconds
Capillary refill	Normal	Prolonged	Minimal response
Extremities	Warm	Cool	Cold, mottled, cyanotic
Urine output	Normal to decreased	decreased/dry diapers	Minimal

foods high in simple sugars (juices, gelatin deserts, large amounts of carbonated soft drinks). Milk products are acceptable if tolerated, and breast feeding should be continued on demand. There is no clinical advantage to using lactose-free or diluted formulas compared with standard formulation.[95] The goal of oral rehydration therapy during the rehydration phase is replacement of the fluid deficit within 3–4 hours, whereas during the maintenance phase both age-appropriate solid foods and fluids are administered. Older children and adults may benefit from the BRAT diet (bananas, rice, apples, toast). However, there is no clinical evidence that the BRAT diet is superior to other recommended diets and the diet is unnecessarily restrictive.[96] The severity of symptoms and dehydration determine the need for hospitalization. Volunteer studies suggest that the administration of bismuth subsalicylate to adults exposed to Norwalk agent reduces the severity and duration of abdominal cramps and the median duration of gastrointestinal symptoms, when compared with the placebo treatment group.[61] The median durations of illness in the treatment and placebo groups were 20 hours and 27 hours, respectively ($p < 0.05$). However, the dose of bismuth subsalicylate was relatively large (30 mL of a 17.6 mg/mL suspension every half-hour after the onset of symptoms for 8 doses, repeated 24 hours later), and clinical relevance of this dose is unclear. The routine use of antidiarrheal agents and antibiotics are not recommended for infants and children with viral gastroenteritis.[97]

IV Seafood

Chapter 28

AMNESIC SHELLFISH POISONING and DOMOIC ACID

HISTORY

In 1987, over 100 Canadians developed gastrointestinal and/or neurological symptoms within 48 hours of ingesting cultured blue mussels (*Mytilus edulis* L.) harvested in the river estuaries of Cardigan Bay, eastern Prince Edward Island. There were 19 hospitalizations among the affected patients and death occurred in 4 elderly patients. Because the neurological symptoms included memory loss, the term *amnesic shellfish poisoning* was used to describe this syndrome. Subsequently, the source of amnesic shellfish poisoning was identified as an amino acid, domoic acid, which originated in some species of phytoplankton. Domoic acid entered the food chain as a result of the bioconcentration of this amino acid in the shellfish. In 1991, an outbreak of gastrointestinal and/or mild neurological symptoms occurred in 21 individuals in Washington state after they consumed Pacific razor clams (*Siliqua patula* Dixon). Although these clams were contaminated with domoic acid, the epidemic was not confirmed as amnesic shellfish poisoning because of the virtual absence of domoic acid from most mussels collected on the coasts of Washington and Oregon.[1] Domoic acid was responsible for the deaths of a large number of brown pelicans and Brandt's cormorants along the Santa Cruz coast in California during 1991.

Domoic acid was initially isolated from the red algae [*Chondria armata* (Kützing) Okamura] in Southern Japan during the late 1950s. This compound was later tested in children as a pediatric antihelmintic for ascariasis.[2] Mass mortality of sea lions and birds along the California and Baja California coast has been associated with high concentrations of domoic acid in food sources (anchovies, sardines).[3,4] In contrast to the contaminated anchovies and sardines, analysis of blue mussels (*Mytilus edulis* L.) collected during this outbreak did not contain toxicologically significant amounts of domoic acid.

EXPOSURE

Although domoic acid originally was isolated from the red algae [*Chondria armata* (Kützing) Okamura], the outbreak of amnesic shellfish poisoning in eastern Prince Edward Island, Canada was associated with marine pennate diatoms from the genus *Pseudo-nitzschia (Pseudo-nitzschia pungens multiseries Hasle)*.[5] Filter-feeding shellfish accumulate domoic acid by direct filtration of affected plankton or by feeding on contaminated organisms. A variety of shellfish bioconcentrate domoic acid including scallops (*Pecten maximus* L.), Pacific razor clams (*Siliqua patula* Dixon), mussels (*Mytilus edulis* L.), Dungeness crabs (*Cancer magister* Dana), cockles (*Cerastoderma edule* L.), and furrow shell (*Scrobicularia plana* da Costa). Some varieties of fish (e.g., anchovy, mackerel, sardine) also accumulate domoic acid, but the concentrations of this toxin in these species is much lower than shellfish, and the domoic acid occurs in the gut of the fish rather than the muscle tissues in shellfish.[6] Additionally, domoic acid accumulates in seaweed harvested from areas with blooms of

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Pseudo-nitzschia species, but the concentrations of toxins are usually not clinically significant. The increased concentrations of domoic acid in shellfish correlate to seasonal variations in phytoplankton blooms. High concentrations of phytoplankton appear in the spring and fall, particularly after periods of heavy rainfall and increased concentrations of nutrients in the water column. Light winds and low water currents allow phytoplankton to accumulate in warmer waters where periods of sunshine promote rapid phytoplankton growth. Other marine organisms capable of producing domoic acid include other *Pseudo-nitzschia* species [*Pseudo-nitzschia australis* Frenguelli, *P. pseudodelicatissima* (Hasle) Hasle], *Alsidium corallinum* C. Agardh, and *Amphora coffeaeformis* (C. Agardh) Kützing.[7,8] Table 28.1 outlines the differences in sources, toxins, and clinical features of amnesic shellfish poisoning and other illnesses associated with seafood-related toxins.

TOXINS

Physiochemical Properties

Domoic acid ($C_{15}H_{21}NO_6$, CAS RN: 14277-97-5, MW 111 Da) is an excitatory neurotransmitter that belongs to the kainoid class of amino acids. Figure 28.1 displays the chemical structure of domoic acid and related isomers. This compound is the principal toxin responsible for amnesic shellfish poisoning.[10] Marine organisms contain at least 10 isomers of domoic acid (isodomoic acids A-H) and domoic acid 5′-diastereomer.[11] However, these isomers are relatively minor constituents (i.e., 10–20%) in marine organisms compared with domoic acid.[12] Domoic acid possesses three carboxyl groups and a secondary amino group with pK_a of 2.10, 3.72, 4.97, and 9.82, respectively. Consequently, domoic acid can exist in valences ranging from –3 to +1 depending on

TABLE 28.1. Toxic Illnesses Associated with Seafood

Illness	Toxin-Producing Organism	Toxins	Clinical Features
Amnesic shellfish poisoning (ASP)	*Pseudo-nitzschia pungens* (Grunow ex Cleve) Hasle	Domoic acid	Nausea, vomiting, disorientation, memory loss, death
Neurotoxic shellfish poisoning (NSP)	*Karenia brevis* (C. C. Davis) G. Hansen et Moestrup	Brevetoxins	Paresthesia, abdominal pain, nausea, diarrhea, dysesthesias, visual changes
Paralytic shellfish poisoning (PSP)	*Alexandrium tamarense* (Lebour) E. Balech, *Alexandrium catenella* (Whedon & Kofoid) E. Balech, *Pyrodinium bahamense* Plate	Saxitoxins	Tingling in the mouth and extremities, dizziness, floating sensation, paralysis, respiratory distress, death
Diarrhetic shellfish poisoning (DSP)	*Prorocentrum lima* (Ehrenberg) Dodge, *Dinophysis fortii* Pavillard, *Dinophysis acuminata* Claparède & Lachmann, *Dinophysis norvegica* Claparède & Lachmann	Okadaic acid, dinophysis toxins, yessotoxin, pectenotoxins	Nausea, vomiting, diarrhea, abdominal pain
Ciguatera	*Gambierdiscus toxicus* Adachi & Fukuyo, *Prorocentrum concavum* Fukuyo, *Prorocentrum mexicanum* Tafall	Ciguatoxins, maitotoxin	Nausea, vomiting, diarrhea, abdominal pain, dizziness, blurred vision, dysesthesias, visual changes, hypotension, respiratory insufficiency; fatalities are rare
Red whelk poisoning	Salivary gland of whelk	Tetramine	Blurred vision, muscular twitching, weakness, headache, ataxia, weakness, paresthesias
Puffer fish poisoning	*Unknown source*[a]	Tetrodotoxin	Paresthesia, floating sensation, dysphagia, hypotension, bradycardia, respiratory distress, ascending paralysis, death
Scombroid fish poisoning	*Morganella morganii* subsp. *morganii* (Winslow et al) Fulton, *Hafnia alvei* Møller, *Klebsiella pneumoniae* subsp. *pneumoniae* (Schroeter) Trevisan, *Proteus* spp., *Vibrio* spp.	Histamine	Nausea, vomiting, diarrhea, headache, flushing, perioral burning, red rash, hypotension

Source: Adapted from Ref 9.

[a]Possible sources include bacteria and actinomycetes in skin gland and ovaries of certain marine puffer fish (e.g., *Fugu rubripes*), such as *Microbacterium arabinogalactanolyticum* (Yokota et al) Takeuchi and Hatano, *Serratia marcescens* subsp. *marcescens* Bizio, *Beneckea alginolytica* (Miyamoto et al) Baumann et al, and *Nocardiopsis dassonvillei* subsp. *dassonvillei* (Brocq-Rousseau) Meyer.

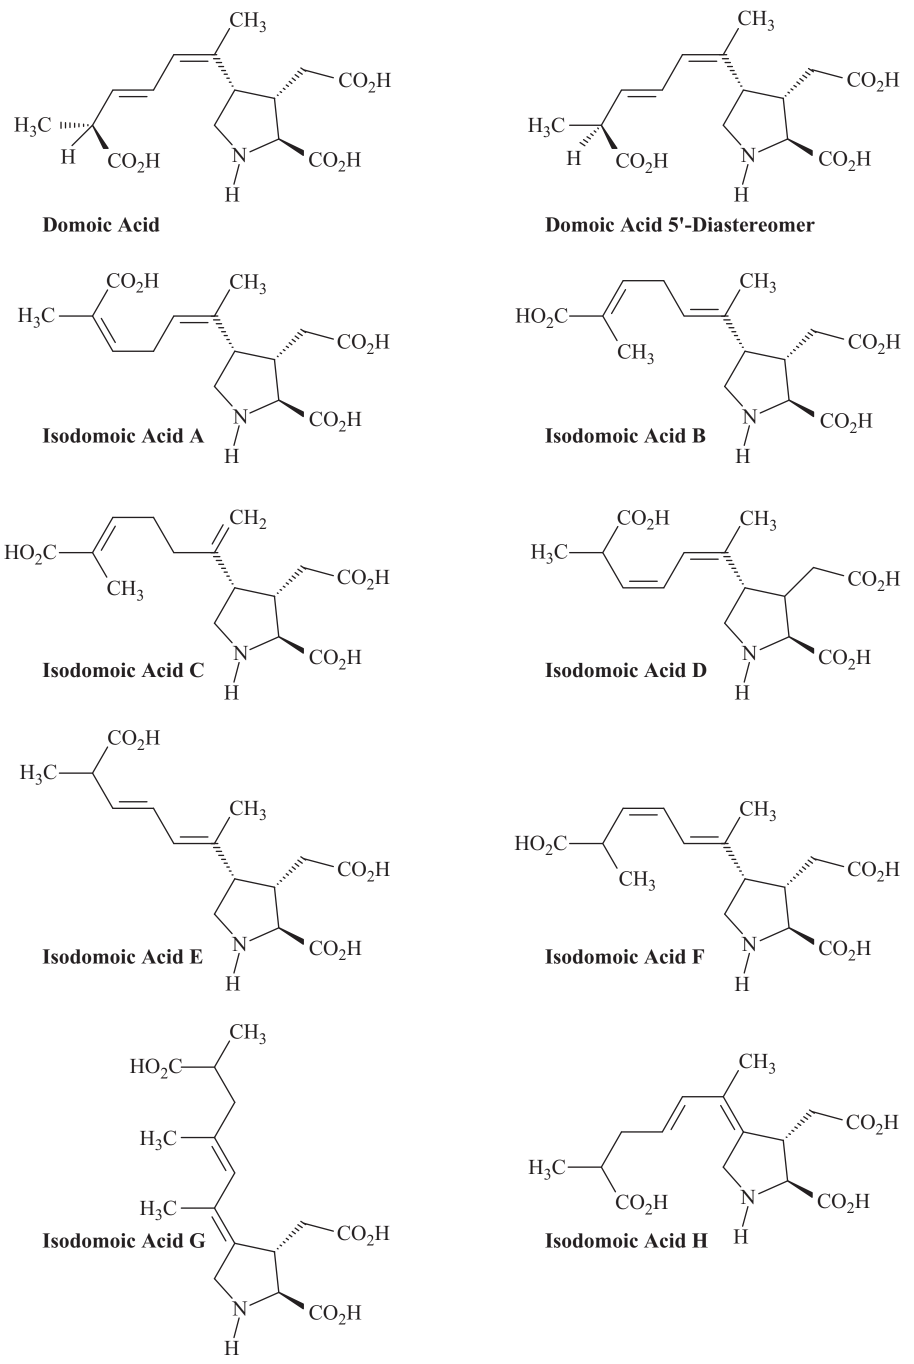

FIGURE 28.1. Chemical structure of domoic acid, isodomoic acids A–H, and 5′-diastereomer.

the pH. At neutral pH, all four groups are charged. Domoic acid and associated isomers are stable at ambient temperatures and in sunlight, but ultraviolet light and heat convert domoic acid to isodomoic acids. At pH 3, about 50% of domoic acid decomposes.[13] Cooking and frozen storage reduces, but does not eliminate domoic acid from food sources.[11]

Toxicokinetics

The elimination of domoic acid varies substantially between shellfish species, ranging from about 1 day in blue mussels (*Mytilus edulis*) to 3 months in razor clams (*Siliqua patula*).[11] Based on limited rodent and primate studies, the absorption of domoic acid is relatively poor

(<4–7%), but once absorbed the distribution and elimination is rapid with elimination half-lives of <2 hours.[14,15]

Mechanism of Toxicity

The two main families of inotropic excitatory amino acid receptors are the *N*-methyl-D-aspartate (NMDA) receptor family and the α-amino-3-hydroxy-5-phenyl-4-isoxazolepropionic acid (AMPA)/kainate receptor family. These ligand-gated cation channels allow the influx of sodium ions into the cell and the efflux of potassium ions from the cell. In the central nervous system, AMPA/kainate channels do not usually allow the entry of calcium into the cell. Receptor cloning studies indicate that there are a large number of potential subtypes of receptors in both of these families.[16] Domoic acid is a potent tricarboxylic agonist at the kainate and α-amino-5-methyl-3-hydroxyisoxazolone-4-propionate (AMPA) subclasses of glutamate receptors. These non-*N*-methyl-D-aspartic acid receptors agonists act as excitatory amino acids along with dicarboxylic amino acids (glutamic acid, aspartic acid).[17] Figure 28.2 demonstrates the structural similarity between domoic acid, kainic acid, and glutamate. Although AMPA receptors mediate fast excitatory synaptic transmission at most excitatory synapses in the central nervous system, the role of kainate receptors in synaptic transmission and neurotoxicity remains unclear. The affinities of domoic acids to the kainate receptors are substantially lower for isodomoic acids than for domoic acid. Although kainate receptors are widely distributed in mammalian brains, these receptors are highly concentrated in the CA3 area of the hippocampus and amygdala.[18] The suspected mechanism of toxicity is the binding of domoic acid to the glutamate receptor with subsequent stimulation causing massive intracellular calcium influx and neuronal death. In addition to neural lesions in the hippocampus, degenerating neuronal cell bodies and terminals also occur in other limbic structures following the administration of parenteral domoic acid including the entorhinal cortex, the subiculum, the piriform cortex, the lateral septum, and the dorsal lateral nucleus of the thalamus.[19] All postmortem examinations of the brains from the four deaths associated with amnesic shellfish poisoning demonstrated prominent necrosis and astrocytosis in the CA1 and CA3 regions of the hippocampus and amygdaloid nucleus. Neurological lesions were also present in the thalamus and subfrontal cortex in some of the postmortem examinations.

DOSE RESPONSE

In animal studies, the parenteral administration of 1–7 mg domoic acid/kg body weight produces characteristic pathological changes in the hippocampus. The toxicity of domoic acid is much lower following oral administration than parenteral use. The intravenous administration of 0.5–1 mg domoic acid/kg body weight to adult monkeys produces focal pathological changes in the CA2 region of the hippocampus, which contains the highest concentration of kainic acid receptor concentration in the brain. Higher doses cause widespread damage to pyramidal neurons and axon terminals of CA1-CA4 and subiculum subfields of the hippocampus.[20] In a study of children with ascariasis, domoic acid was administered at oral doses of 0.6 mg/kg body weight without evidence of adverse effects.[2]

The estimated amount of domoic acid ingested by confirmed cases of amnesic shellfish poisoning during the 1987 epidemic was 60–290 mg/patient. Based on estimations of the amount of mussel tissue ingested during this epidemic, the ingestion of domoic acid >1 mg/kg body weight produced gastrointestinal symptoms and >4.5 mg/kg body weight caused neurological symptoms. The presence of renal dysfunction increased the severity of the adverse effects. During this outbreak, the estimated ingestion of 15–20 mg domoic acid by adults did not produce symptoms.[21] The dose response for consumption of contaminated mussels was highly variable during this outbreak because most people eating these mussels did not develop symptoms, and the amount ingested by severely affected patients did not produce clinically significant symptoms in other individuals.

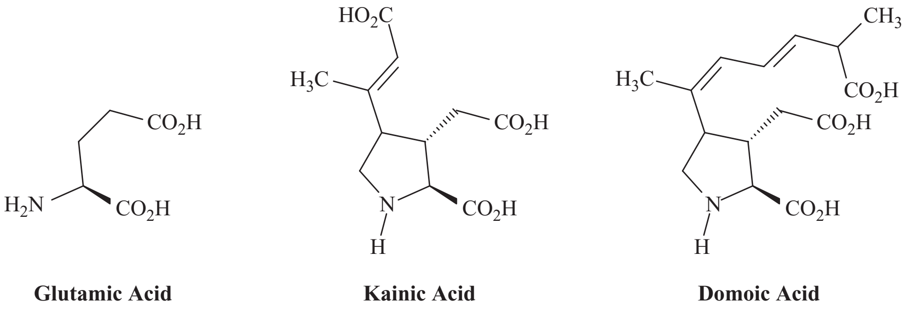

FIGURE 28.2. Structural similarities of domoic acid, kainic acid, and glutamic acid.

CLINICAL RESPONSE

The single, well-documented case series of amnesic shellfish poisonings occurred in Canada during 1987. Clinical effects included gastrointestinal symptoms within 24 hours of mussel consumption and/or neurological symptoms within 48 hr of mussel consumption. The average onset of symptoms in this epidemic occurred about 5 hours after ingestion of the affected mussels. Of the 107 confirmed cases, the most common gastrointestinal symptoms were nausea (80%), vomiting (64%), abdominal cramping (41%), and diarrhea (41%), whereas the most common neurological effects were severe headache (34%), poor balance (33%), and short-term memory loss (26%).[22] The vast majority (i.e., 99%) of individuals consuming the contaminated mussels in this outbreak developed clinically significant illness.[23] Other neurological effects included unsteadiness, confusion, disorientation, agitation, piloerection, pupillary dilation/constriction, and generalized weakness. Most symptoms resolved within 72 hours with the exception of neurological symptoms, which improved up to 3 months after ingestion of affected mussels. Severe effects included focal motor seizures, coma, hypotension, and profuse bronchial secretions, primarily in elderly patients or patients with preexisting illnesses (hypertension, insulin-dependent diabetes, renal dysfunction). A few patients developed transient motor abnormalities (ophthalmoplegia, hemiparesis) during acute amnesic shellfish poisoning. Temporal lobe epilepsy is a potential complication of severe domoic acid intoxication.[24] The occurrence of seizures and memory loss are unique features of amnesic shellfish poisoning when compared with neurotoxic or paralytic shellfish poisoning.

DIAGNOSTIC TESTING

Analytical Methods

Bioassays with mice or rats are the most common methods of detecting algal toxins, but these tests have relatively low sensitivity.[25] Analytical methods for the detection of domoic acid include thin layer chromatography (semi-quantitative), gas chromatography/mass spectrometry after formation of the *N*-formyl-*O*-methyl derivative, and high performance liquid chromatography (HPLC) with UV, mass spectrometric, or fluorescence detection.[11] The limit of detection of the latter is in the range of 1 pg/g material.[26] The AOAC official method of analysis (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) utilizes reverse phase liquid chromatography (RPLC) with UV detection at 242 nm with an analytical range of 20 pg/g of mussel tissue.[27] Competitive enzyme-linked immunoassays can detect domoic acid in plasma and urine at concentrations near 0.2 μg/mL.[28] The use of monoclonal antibodies against domoic acid reduces the limit of quantitation to <0.04 μg/g.[29]

Biomarkers

Domoic acid was not detected in 17 cases of human amnesic shellfish poisoning, when tested over 2 days after the ingestion of affected mussels.[30] The regulatory action limit for domoic acid in mussels developed following retrospective analysis of the Port Edwards outbreak of amnesic shellfish poisoning is 20 μg domoic acid/g mussel tissue, and this value includes a 10-fold safety factor.

Abnormalities

Electroencephalographic examination of severely affected individuals demonstrated moderate to severe generalized slowing of background activity that persisted at least 3 months in some affected patients.[31] Neuropsychological examination revealed anterograde memory disturbance in affected cases and retrograde amnesia in the more severely affected patients. Most patients did not develop global deterioration, and IQ scores remained at premorbid levels with intact language and frontal lobe function. Positron emission tomography (PET) scanning of 4 severely affect patients demonstrated severe reduction of glucose metabolism in the hippocampal and medial temporal lobes, consistent with the areas of the brain associated with short-term and long-term memory.[32]

TREATMENT

Treatment is supportive. Endotracheal intubation may be necessary to protect the airway in severely affected patients with respiratory insufficiency. Patients should be evaluated for oxygen saturation as well as dehydration as a result of the gastrointestinal symptoms associated with amnesic shellfish poisoning. Decontamination measures are not usually necessary because of the common occurrence of vomiting and the possibility of mental status changes. There is no known antidote for amnesic shellfish poisoning. Although there are few clinical data, theoretical considerations suggest that benzodiazepines (diazepam, lorazepam) may control seizures and excessive hippocampal activity.[7]

Chapter 29

AZASPIRACID SHELLFISH POISONING and AZASPIRACID TOXINS

HISTORY

In 1995, 8 people in the Netherlands developed a diarrhetic shellfish-like poisoning after consuming mussels from Ireland. However, the concentrations of okadaic acid and dinophysistoxins were low. Subsequently, a lipophilic, highly oxygenated polyether was isolated from the contaminated mussels that contained a unique azaspiro ring (azaspiracid). A subsequent outbreak of azaspiracid poisoning occurred as a result of the consumption of contaminated mussels from Arranmore Island, Ireland during 1997. Other outbreaks of azaspiracid poisoning occurred in Italy, France, and England as a result of eating contaminated mussels from the Ireland coast.[1] In 2003, Nicolaou et al synthesized azaspiracid-1.[2]

EXPOSURE

Source

Although azaspiracid and azaspiracid analogs are the etiology of a diarrheal illness (i.e., azaspiracid poisoning) associated with eating shellfish, the source of this toxin remains unknown. The most likely source is a dinoflagellate because of the highly oxygenated polyether structure of the toxin and the seasonal occurrence of the diarrheal illness. The suspected producer of azaspiracid compounds is *Protoperidinium crassipes* (Kofoid) Balech, which belongs to the large, ubiquitous group of phytoplankton.[3] The outbreaks of azaspiracid poisoning occurred during the winter season with toxicity persisting from November through April in one outbreak and October through April in another outbreak. Despite widespread distribution of the suspected causative organism, most of the recognized cases of azaspiracid poisoning result from the ingestion of mussels from the northern coast of Europe (England, Ireland, Norway). A survey of blue Mediterranean mussels (*Mytilus galloprovincialis* Lamarck) and the common cockle (*Cerastoderma edule* L.) from the coast of Portugal detected no clinically significant amounts of azaspiracid compounds.[4] However, azaspiracid compounds were detected in mussels from the Spanish and French coasts with toxin profiles similar to contaminated Irish mussels.[5] Although maximum azaspiracid concentrations in shellfish occur in the late summer, azaspiracid poisoning can occur even when marine dinoflagellate populations are low.[6] Contamination of shellfish with azaspiracid compounds occurs in all seasons, but the heaviest contamination occurs in the summer.

Food Processing

Although contaminated mussels are the primary source of azaspiracid poisoning, other bivalve mollusks can accumulate azaspiracid compounds including oysters, scallops, cockles, and clams. Based on analysis of azaspiracid compounds in bivalves from the western coastal region of Ireland, only oysters accumulate similar amounts of these toxins as mussels.[6] However, the ability of oysters to accumulate these toxins is somewhat less than mussels because the latter are cultivated on ropes in relatively deep waters compared

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

with the cultivation of oysters along the shoreline. Azaspiracid compounds (i.e., AZA1) occur primarily in the digestive tracts of bivalve mollusks, but some of these toxins (e.g., AZA3) can diffuse into surrounding tissues.[7] Consequently, the toxin profiles differ between different tissues as well as between individual specimens of bivalve mollusks.[8]

TOXINS

Physiochemical Properties

Azaspiracid (CAS RN: 214899-21-5, azaspiracid-1, AZA1) contains a unique spiro ring assembly, a cyclic amine and a carboxylic acid that is unique among nitrogen-containing toxins found in dinoflagellates and shellfish.[9] After extraction with 80% methanol, 40 kg of mussels (*Mytilus edulis* L.) involved with an outbreak of azaspiracid poisoning at Arranmore Island in November 1997 yielded 11 mg AZA1, 3 mg azaspiracid-2 (AZA2), and 0.6 mg azaspiracid-3 (AZA3). The latter two compounds are 8-methylazaspiracid and 22-demethylazaspiracid, respectively. Typically, AZA1 is the most prevalent azaspiracid compound detected in shellfish.[10] Mouse lethality studies indicate that AZA2 and AZA3 are slightly more potent than AZA1 (0.2 mg/kg).[11] Additional analogs of azaspiracid isolated from this outbreak include azaspiracid-4 (3-hydroxy-AZA3) and azaspiracid-5 (23-hydroxy-AZA3). Mouse lethality studies indicate that these two analogues are about 5 times less potent (i.e., 1 mg/kg) than azaspiracid via intraperitoneal administration in mice.[12] AZA6 is an isomer of azaspiracid, and AZA7–AZA10 are probably products of the biotransformation of azaspiracid compounds in shellfish. Typically, AZA4–AZA5 and AZA7–AZA10 account for <8% and <2%, respectively, of the total amount of azaspiracid compounds extracted from shellfish.[13] Figure 29.1 demonstrates the chemical structures of the five azaspiracid compounds.

Azaspiracid-4 (AZA4)	OH	H	H	H
Azaspiracid-5 (AZA5)	H	H	H	OH

FIGURE 29.1. Chemical structures of azaspiracid and analogues.

Mechanism of Toxicity

The oral administration of azaspiracid to mice produces necrosis of the *lamina propria* of the small intestine as well as necrosis of B cell and T cell lymphocytes in lymphoid tissue of the thymus, Peyer's patches, and spleen. Additionally, fatty changes occur in the liver following the administration of azaspiracid compounds to experimental animals.[14] Mouse bioassays of hexane extracts of mussels associated with azaspiracid poisoning produce respiratory insufficiency, spasm, limb paralysis, and death at higher doses than the dose necessary to produce necrosis in the gastrointestinal tract. The neurological changes and necrosis in the gastrointestinal tract are distinct from histopathology of okadaic acid and diarrhetic shellfish poisoning, and neurological effects have not been reported in human cases of azaspiracid poisoning. The mechanism of these changes remains undefined, but preliminary data suggests that azaspiracid compounds modulate calcium and cyclic adenosine monophosphate (cAMP).[15] Mouse lethality studies indicate that oral and intraperitoneal administration of azaspiracid produce similar toxicity.[14]

DOSE RESPONSE

There are few human data on the dose response of azaspiracid compounds. The European Commission established a maximum limit of 0.16 μg AZA 1–3/g shellfish meat-based animal data.

CLINICAL RESPONSE

The clinical presentation of azaspiracid poisoning is similar to diarrhea shellfish poisoning including the occurrence of nausea, vomiting, severe diarrhea, and abdominal cramps.[1] Although neurological symptoms occur in animal studies of azaspiracid poisoning, human case reports to date do not associate neurologic symptoms with azaspiracid poisoning.

DIAGNOSTIC TESTING

Mouse bioassays are the traditional method for detecting the toxins associated with diarrhetic shellfish poisoning including azaspiracid compounds. However, the conventional mouse bioassay protocols are relatively insensitive to the total azaspiracid content of shellfish.[7] Based on directive 2002/225/EC, the European Commission established a maximum limit of 0.16 µg AZA 1–3/g shellfish meat.[16] Analytical determination of azaspiracid compounds usually involves the combination of liquid chromatography and mass spectrometry or tandem mass spectrometry.[17] Liquid chromatography/electrospray ionization mass spectrometry is a sensitive method of analyzing tissue samples for the major azaspiracid compounds and their hydroxyl analogues with a detection limit near 5 pg.[13] An alternate method for quantifying the amount of AZA-1 through AZA-3 in shellfish tissue involves the use of a single quadrupole mass spectrometer after solid phase extraction.[12] Stobo et al reported a rapid method for the detection of multiple algal toxins including AZA-1 through AZA3 based on liquid chromatography/mass spectrometry.[18] The best-validated method for the detection of AZA-1 is the multiresidue method for the determination of algal toxins in shellfish developed by McNabb et al based on liquid chromatography/tandem mass spectrometry.[19] The limit of detection with this method is <0.02 mg/kg.

TREATMENT

The treatment of azaspiracid poisoning is supportive (antiemetics, antidiarrheal agents). Patients with suspected azaspiracid poisoning should be evaluated for fluid and electrolyte imbalance depending on the severity of the presenting gastrointestinal symptoms. The illness is usually self-limited.

Chapter 30

DIARRHETIC SHELLFISH POISONING and OKADAIC ACID

HISTORY

Although the first suspected cases of diarrhetic shellfish poisoning occurred in the Netherlands during 1961,[1] okadaic acid was first associated with diarrhetic shellfish poisoning in Japan during the late 1970s when Yasumoto and Oshima isolated this compound from the black sponge *Halichondria okadaic*.[2] The first documented outbreak of diarrhetic shellfish poisoning in Europe occurred in 1979.[3] During the 1980s, dinophysistoxins (DTX1, DTX3) were identified as additional causes of diarrhetic shellfish poisoning.[4] Subsequently, several other groups of toxins were associated with phytoplankton-induced diarrhetic shellfish poisoning including yessotoxins and pectenotoxins. Reports of diarrheic shellfish poisoning now occur worldwide, including North and South America, Australia, New Zealand, the former Soviet Union, and Europe (Italy, Sweden, Norway, Portugal, Belgium, Greece).[5]

EXPOSURE

Dinoflagellates, particularly species of the genera *Dinophysis* and *Prorocentrum,* are the primary sources of diarrhetic shellfish-associated toxins in contaminated bivalve mollusks, which accumulate these toxins. The three parent compounds in the group of diarrhetic shellfish poisoning toxins are okadaic acid, dinophysistoxin 1 (DTX1), and dinophysistoxin 2 (DTX2). The distribution of okadaic acid is worldwide (e.g., Japan, Europe, North America),[6] whereas the occurrence of DTX1 (Japan, Norway) and DTX2 (Ireland, Portugal) is more limited.[7,8] The concentrations of these toxins in the digestive glands of bivalve molluscs vary during different seasons depending on the occurrence of associated phytoplankton. In Portuguese coastal waters, *Dinophysis acuminata* Claparède & Lachmann and *Dinophysis acuta* Ehrenberg are the main phytoplankton associated with diarrhetic shellfish poisoning.[7] Okadaic acid predominates in contaminated bivalves during the spring coincident with the appearance of *D. acuminata*, whereas DXT2 appears in the late summer and early autumn when *D. acuta* occurs in coastal waters. During the occurrence of diarrhetic shellfish poisoning on the Spanish coast in 1993, okadaic acid and DTX2 were the primary toxins.[9] In mussels and scallops, other acetylated derivatives ("DTX3") of okadaic acid, DTX1, and DTX2 also occur.[10] In addition to okadaic acid and dinophysistoxins, additional toxins isolated from contaminated bivalves that cause adverse effects in animal studies include pectenotoxins and yessotoxins.[11] However, these latter two groups of toxins have not been associated with human illness, and these compounds do not produce diarrhea in animal studies.[12] Although the highest concentration of okadaic acid and related toxins occur in blue mussels (*Mytilus edulis* L.) and to a lesser extent in scallops, consumption of contaminated gastropods and crustaceans (e.g., brown crab, *Cancer pagurus*) also can cause diarrhetic shellfish poisoning.[13]

Okadaic acid was originally isolated from sponges on the Pacific coast of Japan (*Halichondria okadai* Kadota) and the coast of Florida (*Halichondria melanodocia* De Laubenfels). Sponges and bivalves accumulate okadaic

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

acid from several species of dinoflagellates including *Dinophysis acuminata* Claparède & Lachmann, *Prorocentrum lima* (Ehrenberg) Dodge, and *Prorocentrum concavum* Fukuyo.[14] Other dinoflagellates (e.g., *Dinophysis fortii* Pavillard) in addition to *Prorocentrum lima* (Ehrenberg) Dodge contain a variety of dinophysistoxins including dinophysistoxin-1, a 35-(R)-methyl derivative of okadaic acid.[4,15] Dinophysistoxin-2 occurs in mussels (*Mytilus edulis* L.). The dinoflagellates, *Thalassiosira weissflogii* (Grunow) G. Fryxell & Hasle and *Prorocentrum maculosum* M.A. Faust, contain dinophysistoxin-4 and diophysistoxin-5a and b, respectively.[16,17] Pectenotoxins occur in scallops contaminated with the toxic dinoflagellate, *Dinophysis fortii* Pavillard.[4] Although shellfish poisoning develops from the ingestion of phytoplankton that bloom, the presence of a bloom is not necessary for the development of sufficient quantities of okadaic acid in shellfish to cause diarrhetic shellfish poisoning. A variety of factors affect the concentration of DSP toxins in contaminated bivalves including water temperature, rainfall, and salinity.[18] The marine dinoflagellate *Protoceratium reticulatum* (Claparède & Lachmann) Butschli is a source of yessotoxin.[19]

TOXINS

Physiochemical Properties

Okadaic acid is a lipophilic, polyether derivative of C38 fatty acids. Figure 30.1 displays the chemical structures of okadaic acid and dinophysistoxins 1–3 (DTX1–3). Okadaic acid, DTX1 (polyether carboxylic acid) and DTX 2A-C (isomers of okadaic acid) are the primary toxins involved in diarrhetic shellfish poisoning. Other congeners (DXT3–5, acyl derivatives) probably are precursors of okadaic acid or shellfish metabolites of the active toxins. In food sources (mussels, clams, cockles), these three toxins occur both in free and esterified forms. The esterification of these toxins is relatively less in mussels (family: Mytilidae) than in other commercial bivalves (scallops, oysters, clams, razor clams, cockles).[10] Outbreaks of diarrhetic shellfish poisoning from contaminated scallops and razor clams have been associated with esterified forms of okadaic acid and dinophysistoxins 1and 2.[20] Dinophysistoxin-3 is a mixture of 7-*O*-acyl derivatives of dinophysistoxin-1 also found in mussels.[21] Because of the absence of acylated forms in marine micro algae, the presumed origin of these acylated forms is biotransformation in the bivalves. Toxicokinetic data from intoxicated patients suggests that DTX-3 undergoes biotransformation to DTX-1 prior to the onset of gastrointestinal symptoms.[22] Dinophysistoxin 4, dinophysistoxin 5a, and dinophysistoxin 5b are water-soluble esters that probably result from the storage or biotransformation of primary parent toxins associated with diarrhetic shellfish poisoning.[23] At least 10 pectenotoxins including several metabolites of parent compounds are associated with extracts from outbreaks of diarrhetic shellfish poisoning.[24] These compounds are novel polyether lactones. Yessotoxins are novel polycyclic, disulfated ether toxins. Analogues of yessotoxin include homoyessotoxin and 45-hydroxy-homoyessotoxin. Yessotoxin is structurally related to ciguatoxin. Okadaic acid is a general tumor promotor in various organs via the inhibition of protein phosphatase-1 and protein phosphatase-2A.[25] The natural marine toxins, calyculin A and microcystin-LR, also inhibit these protein phosphatases, and these latter compounds are tumor promoter on mouse skin and rat glandular stomach.[26] The parent toxins (okadaic acid, DTX1, DTX2) associated with diarrhetic shellfish poisoning are lipophilic, and these compounds accumulate in the digestive glands of

FIGURE 30.1. Chemical structure of okadaic acid and dinophysistoxins.

bivalves filtering dinoflagellates contaminated with these toxins.

Mechanism of Toxicity

Okadaic acid and dinophysistoxins-1 inhibit serine and threonine protein phosphatases, which regulate metabolic processes in eukaryotic cells. Diarrhea develops from increased calcium influx, prostaglandin production, and the secretion of fluid into mucosal cells in the gastrointestinal tract as a result of the accumulation of phosphorylated proteins. Yessenotoxins do not inhibit protein phosphatases, and these compounds probably do not produce diarrhea based on animal studies.[27] Pectenotoxins are tumor promoters that cause apoptosis in rat hepatocytes, but their role in diarrhetic shellfish poisoning remains unclear.[24]

DOSE RESPONSE

The ingestion of 40–50 µg okadaic acid is the approximate threshold of toxicity for the development of diarrhea; this dose is equivalent to the ingestion of about 300 grams of mussel meat containing 160 µg okadaic acid/kg.[28] A maximum concentration of 80 µg okadaic acid/kg in whole shellfish meat is equivalent to a maximum concentration of 400 µg okadaic acid/kg hepatopancreas. During an outbreak of diarrhetic shellfish poisoning in Japan, the estimated ingestion of 12 mouse units (48 µg okadaic acid equivalents) was the lowest dose associated with mild gastrointestinal symptoms.[2] In animal studies, the oral administration of 50 µg okadaic acid/kg body weight did not produce observable adverse effects, whereas the oral administration of 90 µg/kg caused diarrhea within 8 hours of dosing.[29] Dose response depends on the toxin profile; therefore, there is substantial variation in the effect of a specific dose as defined by the mouse assay.

CLINICAL RESPONSE

Diarrhetic shellfish poisoning is a mild, self-limited gastrointestinal illness, manifest primarily by profuse diarrhea. The gastrointestinal symptoms of diarrhetic shellfish poisoning typically begin within a half hour to a few hours (i.e., up to 5–6 hours) after consumption of toxic shellfish. Adverse gastrointestinal effects include abdominal cramps, nausea, vomiting, and profuse diarrhea that can cause significant fluid and electrolyte loss.[20] Other symptoms include headache, fever, and chills.[30] Symptoms resolve within 3 days. Fatalities do not usually occur, and neurological symptoms are not associated with diarrhetic shellfish poisoning.

DIAGNOSTIC TESTING

Analytical Methods

Bioassay is the most common method of identifying toxins associated with diarrhetic shellfish poisoning. More-specific analytical methods include immunoassays, protein phosphatase assays, high performance liquid chromatography (HPLC) based on precolumn derivatization with fluorescence, and liquid chromatography with mass spectrometry (LC/MS).[3,31] The determination of individual toxins associated with diarrhetic shellfish poisoning requires chromatographic separation prior to analysis. Quantitative determination of toxins associated with diarrhetic shellfish poisoning by LC/MS allows determination of the concentration of these toxins in the range of 5–40 ng/g muscle tissue.[32] The use of combined LC/MS with electrospray ionization allows the separation of diarrhetic shellfish poisoning (DSP) toxins including okadaic acid, dinophysistoxins, pectenotoxins, and yessotoxins.[33] High performance capillary electrophoresis is an alternative to HPLC for the analysis of yessotoxins.[34] The inclusion of yessotoxins and pectenotoxins in extracts for testing the presence of diarrhetic shellfish poisoning toxins depends on the extraction process because acetone, but not ether, extracts these two toxins.

Biomarkers

Analysis of a marine phytoplankton biomass consisting primarily of *Dinophysis acuta* demonstrated average okadaic acid and the isomer (DTX-2) concentrations of approximately 60 pg/cell and 80 pg/cell, respectively, as measured by liquid chromatography coupled with electrospray mass spectrometry and tandem mass spectrometry.[35] Most countries use the mouse bioassay as a means to monitor the presence of okadaic acid in mussels and other commercial bivalves. One mouse unit corresponds to about 4–5 µg okadaic acid.[36] For most countries, the acceptance limit for okadaic acid is approximately 20–25 µg equivalents. Most countries set the acceptable limits for DSP toxins in the hepatopancreas of bivalve molluscs at 0.8–2 µg/g tissue. There is substantial variation in the DSP toxins in adjacent and geographically separated mussels.[8]

TREATMENT

Treatment is supportive. Patients should be evaluated for fluid and electrolyte imbalance as a result of profuse diarrhea and vomiting. Decontamination measures are not necessary.

Chapter 31

NEUROTOXIC SHELLFISH POISONING and BREVETOXINS

HISTORY

Neurotoxic shellfish poisoning was first recognized in bivalves from the Gulf of Mexico during the 1950s. Historically, neurotoxic shellfish poisoning results from the ingestion of bivalves from two areas: the Haruaki Gulf in New Zealand and the Gulf of Mexico near southwest Florida and Texas.[1,2]

EXPOSURE

Consumption of brevetoxin-contaminated bivalves (Pacific oysters, greenshell mussels, clams, cockles) produces neurotoxic shellfish poisoning. The source of neurotoxic shellfish poisoning is the dinoflagellate *Karenia brevis* (C.C. Davis) G. Hansen & Ø. Moestrup (*Gymnodinium breve, Ptychodiscus brevis*). Brevetoxins and some polar metabolites accumulate in filter-feeding bivalves. Blooms (red tides) of *Karenia brevis* occur annually in Florida coastal waters, and these events cause severe rhinitis, pulmonary hemorrhage and edema, hemosiderosis, nonsuppurative leptomeningitis, and death in marine animals including manatees.[3] These dinoflagellates are relatively fragile, and mild wave action along the beaches results in the release of toxins into the water and ocean spray. Marine organisms (e.g., whelks), which prey on contaminated filter-feeding bivalves (e.g., *Chione cancellata* L., *Mercenaria* spp.) can accumulate sufficient brevetoxins to produce neurotoxic shellfish poisoning.[4] Toxic red tides associated with *Karenia brevis* also occur in New Zealand.[5]

TOXINS

Physiochemical Properties

The ingestion of brevetoxins causes neurotoxic shellfish poisoning. These lipid soluble, cyclic polyether compounds are neuroexcitatory toxins similar to ciguatera toxin. Brevetoxins PbTx-1 (brevetoxin A, CAS RN: 98112-41-5), PbTx-2 (brevetoxin B, CAS RN: 79580-28-2), and PbTx-3 (brevetoxin T17, CAS RN: 85079-48-7) were isolated from cultures of *Karenia brevis* under controlled conditions in the ratio of 1:7:2; therefore, PbTx-2 and PbTx-3 probably are the major toxins produced by this dinoflagellate.[6,7] Brevetoxins are tasteless, odorless, heat stable, and acid stable. In a study of neurotoxic shellfish poisoning in the Gulf of Mexico, the predominant brevetoxin was PbTx-2 (brevetoxin B) with the concentrations of Pb-Tx-1 and Pb-Tx-3 being about 10 times less than the concentration of brevetoxin B in seawater extracts as measured by liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry (HPLC/APCI/MS).[8] Metabolites (BTX) of these parent brevetoxin compounds occur as these toxins accumulate in the food chain, and bivalve mollusks biotransform parent brevetoxins via species-specific pathways.[9] Most bivalves have the ability to transform PbTx-2 to the reduction product, PbTx-3, and the oxidation product BTX-B5 with subsequent conversion of BTX-B5 to BTX-B1.[10] In a study of an outbreak of neurotoxic shellfish poisoning in New Zealand, brevetoxin metabolites present in New Zealand cockles

(*Austrovenus stutchburyi* Wood) included BTX-B5 and BTX-B1 (N-taurine conjugate of BTX-B5). Analysis of the hepatopancreas of the greenshell mussel (*Perna canaliculus* Gmelin) indicated the presence of the following metabolites: BTX-2, BTX-3, and BTX-B4 (mixture of *N*-myristoyl-BTX-B2 and *N*-palmitoyl-BTX-B2).[11,12] Figure 31.1 demonstrates the chemical structure of brevetoxin metabolites and proposed metabolic pathway for the biotransformation of PbTx-2. In whelks preying on brevetoxin-contaminated bivalves, the predominant brevetoxin was PbTx-3, which is a metabolite of the parent toxin, PbTx-2.[4]

Mechanism of Toxicity

Brevetoxins are depolarizing compounds that bind to site 5 on the voltage-gated sodium channel, resulting in persistent activation and prolonged opening of the sodium channel of nerve and muscle cells. Some

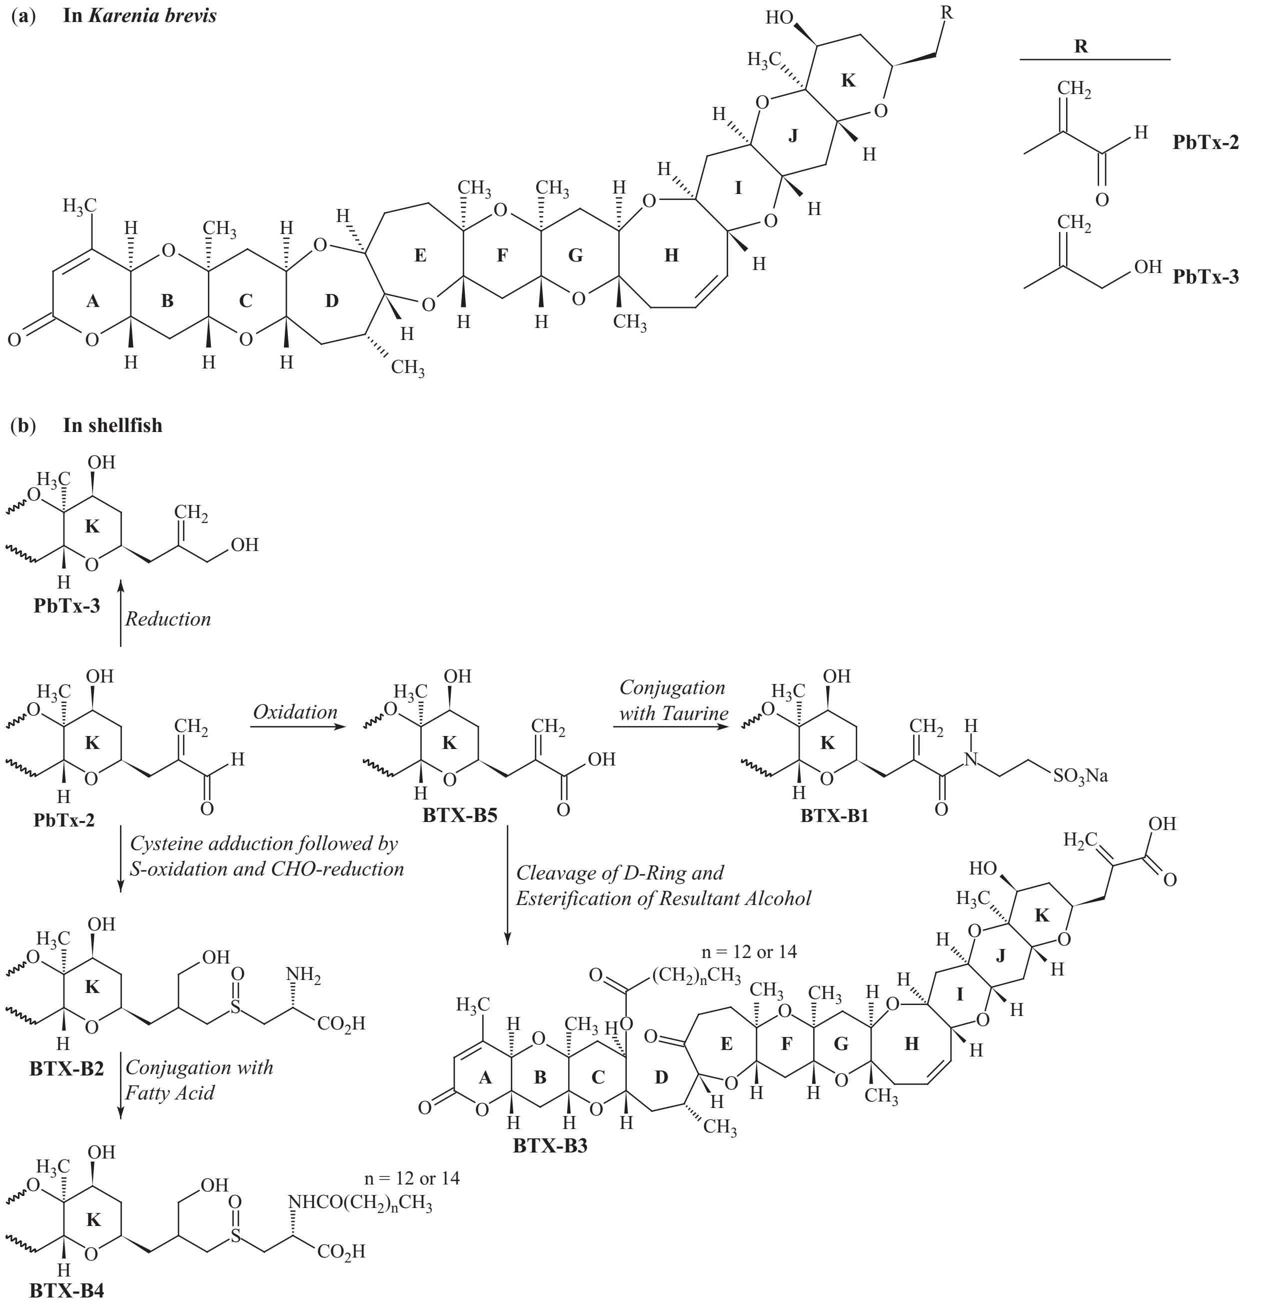

FIGURE 31.1. Chemical structures and suggested metabolic pathway of PbTx-2 biotransformation.

brevetoxin metabolites act as partial agonists at site 5.[13] Ciguatoxin also binds to the same site, but the affinity of ciguatoxin for site 5 is much greater than brevetoxins. Batrachotoxin, veratridine, and aconitine interact at a different site (i.e., site 2) on the voltage-gated sodium channel. Results of the effect of brevetoxin on the sodium channel include shift of activation potential to more negative membrane potentials, prolongation of open time, inhibition of channel inactivation, accumulation of intracellular sodium, and induction of subconductance states.[14]

DOSE RESPONSE

There are few data on the effects of specific doses of brevetoxins on humans. The current US guideline for prohibition of shellfish harvesting is >20 MU/100 g shellfish tissue based on animal studies.

CLINICAL RESPONSE

Neurological Effects

Neurotoxic shellfish poisoning is a relatively mild illness that causes gastrointestinal and excitatory neurological symptoms similar to mild ciguatera poisoning.[15] Both brevetoxins and ciguatoxins enhance sodium entry into cells by binding to site 5 on the voltage-sensitive sodium channel. Neurotoxic shellfish poisoning consists of gastrointestinal irritation and sensory disturbances of the face and extremities including painful sensations (cold allodynia) following exposure to cold objects similar to ciguatera fish poisoning. Symptoms of neurotoxic shellfish poisoning usually develop within a few minutes to 3 hours after ingestion of contaminated bivalves, manifest by perioral paresthesias, loss of coordination, myalgias, and gastrointestinal distress (nausea, vomiting, diarrhea, abdominal cramps). Case series suggest that some differences in clinical patterns between different outbreaks of neurotoxic shellfish poisoning can occur as a result of differences in the toxin profile. The median onset of illness in a series of 48 cases of neurotoxic shellfish poisoning from North Carolina was 3 hours with a range up to 18 hours.[15] The typical pattern of intoxication involves the onset of gastrointestinal distress and perioral numbness followed by progressive paresthesias of the trunk and extremities as well as mild muscle weakness.[16] Occasionally, ataxia, vertigo, or classical muscarinic symptoms (lacrimation, salivation, rhinorrhea, bronchorrhea, miosis, urination, defecation) can occur.[17] Symptoms usually resolve within 1–2 days. Muscle paralysis, cranial nerve dysfunction, respiratory insufficiency, and death from neurotoxic shellfish poisoning does not usually occur.

Respiratory Effects

Contact with aerosols generated by wave action during blooms of *Karenia brevis* can cause conjunctival and upper respiratory tract irritation, rhinitis, cough, and bronchoconstriction.[18] An observational study of 59 subjects with physician-diagnosed asthma demonstrated a small (i.e., 10%), acute reduction in forced expiratory volume in 1 second (FEV_1) during exposure to brevetoxins from a Florida red tide, when compared with baseline one hour prior to exposure.[19] These subjects reported mild respiratory irritation, but none of the subjects required medical treatment. A similar study of 28 healthy lifeguards also reported mildly increased respiratory symptoms (eye and throat irritation, cough, headache) during exposure to a Florida red tide, but there were no significant changes in pulmonary function during mild exercise.[20]

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect brevetoxins include radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), high performance liquid chromatography/mass spectrometry (HPLC/MS), and mouse bioassay.[4,21] The mouse bioassays of diethyl ether extracts from affected shellfish are the most common method of confirming the presence of brevetoxins in contaminated bivalves. One mouse unit is the amount of crude toxic residue that will kill 50% of the test animals (i.e., 20-gram mice) in about 15 hours. The mouse bioassay underestimates the composite toxicity of brevetoxin-contaminated shellfish compared with cytotoxicity assays, but the latter probably overestimates composite toxicity because of sensitivity to less toxic brevetoxin metabolites.[8] A competitive enzyme-linked immunosorbent assay using goat antibrevetoxin antibodies was developed for the monitoring of brevetoxins in bivalves.[22] The detection limit for brevetoxins in spiked oysters was 2.5 μg/100 g shellfish meat. More specific methods for the determination of brevetoxins involve liquid chromatography with mass spectrometry and tandem mass spectrometry. At a signal-to-noise ratio of 5, the limits of quantitation for BTX-B1 and PbTx-3 were 0.4 ng/g and 2 ng/g, respectively.[23]

Biomarkers

Brevetoxins are rapidly eliminated from the blood. Case reports indicate that brevetoxins remain in the urine <4 days with high concentrations (i.e., 100 ng/mL) present during the first 24 hours after onset of illness as measured

by HPLC/MS.[4] The current US guidance level for prohibition of shellfish harvesting as a result of elevated brevetoxin concentrations is >20 MU/100 g shellfish tissue.

TREATMENT

Treatment is supportive. In contrast to ciguatera fish poisoning, complete recovery from neurotoxic shellfish poisoning usually occurs within a few days. Inhaled bronchodilators (e.g., albuterol) may be necessary for the treatment of bronchospasm.

Chapter 32

PARALYTIC SHELLFISH POISONING and SAXITOXINS

HISTORY

References to red tides have appeared since Biblical times as noted by the following passage from Exodus 7:20–21: “All the water of the river was changed into blood. The fish in the river died and the river itself became so polluted that the Egyptians could not drink the water.” The Iliad describes red tides and ancient Greeks named the Red Sea for the occasional occurrence of reddish waters that probably occurred as a result of phytoplankton blooms.[1] Clinical syndromes consistent with paralytic shellfish poisoning occurred in Europe during the 17th century and during the exploration of North America in the 18th century. Scientific reports of paralytic shellfish poisoning appeared in the 19th century.[2] The red tides represent the proliferation or “bloom” of dinoflagellates that can produce neurotoxins including the saxitoxins associated with paralytic shellfish poisoning. Bivalve mollusks accumulate these neurotoxins during the filtering of water for food. The parent toxin, saxitoxin, was isolated from the giant Alaskan butter clam (*Saxidomus giganteus* Deshayes) and the California mussel (*Mytilus californianus* Conrad) in 1957.[3] Saxitoxin was first synthesized in 1977 by Tanino et al.[4]

EXPOSURE

Source

Filter-feeding bivalve mollusks (mussels, clams, oysters, scallops, cockles, warty venus) concentrate saxitoxins and gonyautoxins synthesized by species from several genera of dinoflagellates (plant kingdom division, Pyrrophycophyta) including *Alexandrium* [*A. tamarense* (Lebour) E. Balech, *A. catenella* (Whedon & Kofoid) E. Balech, *A. minutum* Halim], *Gymnodinium* (*G. catenatum* L.W. Graham),[5] *Gonyaulax*, and *Pyrodinium* (*P. bahamense* Plate).[6] The distribution of dinoflagellates from the genus *Alexandrium* is global compared with the more local distribution (e.g., Mexico, Argentina, Spain, Tasmania, Japan) of *Gymnodinium catenatum*. Mussels and clams are the most common source of paralytic shellfish poisoning,whereas the most prominent dinoflagellate in European waters is *Alexandrium tamarense*.[7] Dinoflagellates occur worldwide in temperate and tropical waters, and cases of paralytic shellfish poisoning occur throughout coast waters around the world (Europe, China, North America, South America, Australia, Mediterranean Sea). Other shellfish contaminated by these dinoflagellates include crustaceans, bivalve mollusks, gastropod mollusks, and cephalopods (octopus, cuttlefish, squid). Crustaceans (shrimp, lobster, crab), gastropod mollusks (whelk, abalone), cephalopods, and finfish do not feed on phytoplankton; therefore, paralytic shellfish poisoning is not usually associated with the consumption of these types of seafood.[8] Crabs and lobsters may transmit paralytic shellfish poisoning toxins when they prey on contaminated mussels and algae cysts. These dinoflagellates survive the winter as cysts, and then transform into motile vegetative forms that cause algal blooms during the summer when water temperatures, nutrients, and pH favor their growth. These blooms last approximately 2–3 weeks until

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

nontoxic phytoplankton replace saxitoxin-forming dinoflagellates.[9] The digestive gland (hepatopancreas) of the lobster may contain paralytic shellfish poisoning toxins, but the amount of these toxins in the tail and claw is usually negligible compared with the hepatopancreas.[10] These toxins also have been reported in other marine animals that are not filter-feeders including the horseshoe crab, xanthid crabs,[11] marine snails,[12] starfish,[13] and puffer fish.[14] These animals also frequently contain tetrodotoxin, which produces pharmacologically similar effects as paralytic shellfish poisoning toxins and palytoxin.[15] In puffer fish, paralytic shellfish poisoning toxins (i.e., usually saxitoxin) always occur with tetrodotoxin, but the concentrations of paralytic shellfish poisoning toxins are substantially lower than tetrodotoxin depending on the puffer fish organ examined.[11,16] The bioconcentration of paralytic shellfish poisoning toxins in affected mollusks does not obviously affect the health of these animals.

About 300 of 5,000 marine species of phytoplankton can cause red tides, but most of these species do not produce clinically significant toxins.[17] Red tides become visible when the concentration of dinoflagellates exceeds 20,000/mL. Paralytic shellfish poisoning usually occurs during summer months along with relatively high water temperature from May to November. Some bivalve species contain paralytic shellfish poisoning toxins during the whole year.[5] Visible blooms are not necessary for bivalve mollusks to accumulate toxic concentrations of these toxins.[18] In addition to dinoflagellate sources, several species of cyanobacteria [e.g., *Aphanizomenon flos-aquae* (Linnaeus) Ralfs ex Bornet & Flahault, *Anabaena circinalis* Rabenhorst, *Lyngbya wollei* (Farlow) Farlow, *Cylindrospermopsis raciborskii* (Woloszynska) Seenaya & Subba Raju] can produce these toxins.[19,20]

Food Processing

Saxitoxin is a water-soluble and heat-stable guanidinium compound that decomposes in alkali media. Steaming and cooking do not significantly reduce the potency of saxitoxin, and commercial food processing does not eliminate the potential for developing paralytic shellfish poisoning from contaminated bivalves.[21] Although steaming and boiling can leach some of the water-soluble paralytic shellfish poisoning toxins from mollusks, heat does not destroy sufficient amounts of these compounds to prevent paralytic shellfish poisoning.[22] Boiling for 20 minutes reduced the saxitoxin concentration in the hepatopancreas of lobsters 60%, whereas the concentration of gonyautoxins 2 and 3 decreased by almost 100%.[17]

TOXINS

Physiochemical Properties

There are over 25 hydrophilic, nonprotein saxitoxin congeners associated with paralytic shellfish poisoning that include carbamates (saxitoxin, neosaxitoxin, gonyautoxins 1–4), sulfocarbamoyl compounds (gonyautoxins 5–6, fractions C1–4), and decarbamoyl derivatives. These compounds are relatively small, substituted dibasic tetrahydropurine compounds with molecular weights ranging from 280–450 Da. Saxitoxin (CAS RN: 35523-89-8) is a carbamate (tetrahydropurine derivative), which is colorless, odorless, water-soluble, and heat stable with a molecular weight of 299 Da. Strong alkali inactivates saxitoxin. The molecular formula of saxitoxin is $C_{10}H_{17}N_7O_4$, and saxitoxin has two pK_a values (8.2, 11.5). Neosaxitoxin is *N*-1-hydroxysaxitoxin, which can be converted to saxitoxin in bivalve mollusks.[23] This compound has local anesthetic properties based on preliminary human studies.[24] Gonyautoxins I–IV are sulfates of hydroxysaxitoxin (II, III) and hydroxyneosaxitoxin (I, IV).[25] The difference in toxin profiles between cultured extracts of dinoflagellates and bivalve mollusks suggests that some carbamate and decarbomyl toxins are converted by the mollusks from parent toxins in the filtered dinoflagellates.[26] Figure 32.1 displays the chemical structures of some paralytic shellfish poisoning toxins. In general, carbamate compounds (e.g., saxitoxin) are the most potent toxins with decarbamoyl and sulfocarbamoyl compounds being progressively less toxic, based on mouse bioassays.[27] For example, the toxin profile of the dinoflagellate *Gymnodinium catenatum* from a Spanish outbreak of paralytic shellfish poisoning contained about 90–95 mole % sulfocarbamoyl toxins.[26] However, these toxins accounted for 26% of the total toxicity as measured by saxitoxin equivalents compared with 73% for the much smaller amount of saxitoxin. Under acidic conditions, sulfocarbamoyl compounds convert to the corresponding carbamate. The profile of paralytic shellfish poisoning toxins varies between season, dinoflagellate, and bivalve species even in the same species harvested at the same location.[5,11]

Toxicokinetics

The biological half-life of these toxins is relatively short (90 minutes) with elimination primarily by glomerular filtration.[28,29] There is limited biotransformation of paralytic shellfish poisoning toxins. Postmortem analysis of these toxin profiles in samples from urine and stomach fluid suggest that biotransformation includes oxidation of the N_1 group on saxitoxin to form the hydroxy

analogue (neosaxitoxin) and hydrolysis of carbamoyl group to form decarbamoyl analogues (GTX3/DTX2 epimers).[30] Some of these metabolites are also excreted in the bile.[31]

Mechanism of Toxicity

Saxitoxin reversibly binds to site 1 on the outer ion conduction pore of the voltage-sensitive sodium channel, producing inhibition of conduction and disruption of the action potential.[32] Site 1 is located on the SS1–SS2 segments of all four domains of the channel protein. Gonyautoxins are sulfated saxitoxin analogs that also bind site 1 of the sodium channel.[33] Saxitoxin blocks the influx of sodium into the cell, but this toxin does not block potassium efflux. However, *in vitro* studies indicate that saxitoxin inhibits L-type Ca^{2+} currents,[34] and modifies the hERG K^+ channel, resulting in slower opening during depolarization and faster closure during repolarization.[35] The interruption of the excitation current in the presence of saxitoxin ultimately causes neuromuscular paralysis. Saxitoxin suppresses AV nodal conduction, reduces peripheral nerve conduction, and depresses the medullary respiratory center. Death usually results from respiratory depression and apnea. In animal studies, high doses of saxitoxin produce hypotension, cardiac failure, and cardiopulmonary arrest.[28]

DOSE RESPONSE

There is no direct correlation between the size of the mollusk and the presence of paralytic shellfish poisoning toxins.[36] During periods of red tides, mussels can accumulate up to 9 mg saxitoxin equivalents; however, the amount of saxitoxin equivalents in seafood does not correlate to toxicity. The amount of saxitoxin equivalents associated with illness and fatalities is highly variable as a result of individual susceptibility, specificity of analytical methods, composition of saxitoxin congeners, and recall bias. Reported ranges of saxitoxin equivalents associated with illness and fatalities from these toxins are 144–1660 µg/person and 300–12,400 µg/person, respectively.[37] A case report associated ingestion of 2,600 µg saxitoxin equivalents (36 µg/kg body weight) with complete paralysis and respiratory failure.[38] Severe illness (coma, respiratory failure, hypertension) was associated with the ingestion of an estimated 411 µg saxitoxin equivalents/kg composed primarily of C1, C2, and gonyautoxins.[39] The estimated ingestion by 4 patients with respiratory arrest from paralytic shellfish

poisoning ranged from 230–411 μg saxitoxin equivalents/kg body weight (paralytic shellfish poisoning toxin profile not stated).[40] During an Alaskan epidemic of paralytic shellfish poisoning, all patients ingesting >37 mg saxitoxin equivalents became ill.[41] The estimated mean dose ingested by 33 ill and 10 asymptomatic individuals was 19.5 mg (range: 0.01–123 mg) and 13 mg (range: 0.02–37 mg), respectively.

CLINICAL RESPONSE

The clinical presentation of paralytic shellfish poisoning is similar to the effects of puffer fish poisoning, which results from the blockade of sodium channels in neurons by tetrodotoxin. The onset of symptoms following the ingestion of saxitoxin-contaminated bivalves is rapid with paresthesias of the face, tongue, and lips beginning within 1–2 hours after ingestion.[42] In a study of 224 confirmed cases in the Philippines, the median onset of symptoms was 5.6 hours with a range up to 34 hours.[36] Similar to tetrodotoxin intoxication, the rapid onset of symptoms from paralytic shellfish poisoning correlates to severity, and death usually occurs within 12 hours of ingestion. The paresthesia and tingling progressively involve the trunk and extremities over the next 1–2 hours, and cranial nerve dysfunction (diplopia, dysarthria, dysphagia, hoarseness) can develop. The onset of neurological symptoms >10–12 hours after ingestion suggests an etiology other than paralytic shellfish poisoning. Severe cases are associated with muscle weakness, ataxia, fixed and dilated pupils, absent or diminished deep tendon reflexes, and paralysis.[40,43] Case reports suggest that patients with paralytic shellfish poisoning retain consciousness at least during the early phase of complete paralysis.[38] In some case series, children under 6 years of age appear more susceptible than adults to these toxins.[44] Some autonomic dysfunction (diaphoresis, tachycardia, excessive salivation, hypertension) can occur. Nonspecific symptoms include headache, thirst, myalgias, low back pain, and vertigo. Peripheral vasodilation secondary to smooth muscle relaxation can cause hypotension. Table 32.1 lists the symptoms associated with paralytic shellfish poisoning in Alaska over an approximate 20-year period. Death is rare and results from respiratory insufficiency secondary to paralysis of muscles in the chest wall and diaphragm typically within 12 hours after ingestion. The patient remains alert during the course of intoxication while vital signs remain stable. Gastrointestinal complaints (nausea, vomiting, abdominal pain) are usually mild or absent. The ingestion of ethanol does not exacerbate the symptoms associated with paralytic shellfish poisoning. Neurological symptoms typically resolve in 12–48 hours.[42] The older medical literature suggests that weakness and fatigue can persist for weeks after intoxication, but the extent of chronic sequelae are not well documented.[45] Chronic exposure to saxitoxin does not reduce toxicity. The differential diagnosis includes Guillain Barré syndrome, botulism, ciguatera, puffer fish poisoning (tetrodotoxin), and organophosphate poisoning.

TABLE 32.1. Symptoms Associated with 117 Cases of Paralytic Shellfish Poisoning in Alaska 1973–1992

Symptom	Cases Present (*N* = 117)
Paresthesias	113
Perioral numbness	64
Perioral tingling	61
Nausea	45
Extremity numbness	43
Extremity tingling	39
Vomiting	34
Weakness	33
Ataxia	32
Shortness of breath	29
Dizziness	28
Floating sensation	24
Dry mouth	23
Diplopia	19
Dysarthria	16
Diarrhea	10
Dysphagia	6
Limb paralysis	4

DIAGNOSTIC TESTING

Analytical Methods

Contamination by saxitoxin is measured by a mouse bioassay in mouse units (MU/mg) as determined by the AOAC International official method of analysis for paralytic shellfish poisoning (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/).[46] Typically, the results of this bioassay are determined as mouse units and, less often as micrograms of poison per 100 g of shellfish tissue. The mouse unit is defined as the amount of toxin required to kill a 20-gram white mouse within 15 minutes following intraperitoneal administration. By definition, one mouse unit equals 0.18 μg saxitoxin equivalents.[21] In the European Union, the maximum acceptable content of paralytic shellfish poisoning toxins in bivalve mollusks is 80 μg/100 g tissue (EEC directive 91/492).[47] The current reference method in the European Union is the mouse bioassay. The presence of many congeners of saxitoxin complicates the analysis of paralytic shellfish poisoning toxin in biological tissues, and the biological assay does

not determine the profile of the many paralytic shellfish poisoning toxins. More sensitive methods (e.g., chromatography) are preferable to biological assays. The most common analytical technique for the separation of PSP toxins is reversed phase high performance liquid chromatography (RP/HPLC) using ion-pairing reagents and postcolumn reaction permitting fluorescence detection. However, there is substantial interlaboratory variation in results from liquid chromatography methods with precolumn derivatization, followed by fluorescence detection.[48] Complete chromatographic separation (e.g., HPLC) of all paralytic shellfish poisoning toxins is necessary prior to quantitation with a fluorescence detector.[25] The use of standard methods of acid solvent extraction (0.1 N HCl) with heating to 100 °C (212 °F) for 5 minutes converts *N*-sulfocarbamoyl toxins into their respective carbamate toxins. Positive findings are usually confirmed with mass spectrometry. For diagnostic purposes, human specimens should be collected immediately because of the rapid elimination (<24 hours) of paralytic shellfish poisoning toxins from the blood. Both urine and blood samples should be collected and frozen for transport to specialty laboratories. The second AOAC official method of analysis for saxitoxin is a HPLC method with prechromatographic oxidation and fluorescence detection.[49] This method allows determination of individual toxins with results reported as μg/kg.

Abnormalities

Normal repetitive stimulation on electrophysiological testing distinguishes paralytic shellfish poisoning from botulism, and the F-wave remains normal during paralytic shellfish poisoning intoxication in contrast to Guillain-Barré syndrome. During an outbreak of paralytic shellfish poisoning that did not cause respiratory depression or hypotension, electrophysiological examination of 8 of 9 patients revealed normal motor and sensory conduction with normal amplitudes.[50] Proximal conduction times were delayed as assessed by decreased F wave latencies and frequencies. Peripheral and central sensory conduction was normal as assessed by somatosensory-evoked potentials. Routine biochemical and hematological tests are usually normal. A case report associated elevated creatine kinase MB fractions with paralytic shellfish poisoning, but there was no definite evidence of myocardial injury on electrocardiogram.[51]

TREATMENT

Treatment is supportive. The most serious complication is respiratory depression, and patients should be evaluated for the adequacy of respirations with pulse oximetry and arterial blood gases as needed. Emesis is not recommended because of the potential of respiratory depression and dysphagia. Although experimental studies suggest that activated charcoal (50 g adult, 1 g/kg children) can bind saxitoxin, there are no clinical data to indicate that the administration of activated charcoal improves clinical outcome. There are no antidotes. Metabolic acidosis should be corrected because of the potential of acidosis to exacerbate the toxicity of paralytic shellfish poisoning toxins in animal studies,[52] but there are inadequate clinical data to determine if serum alkalinization improves outcome. Patients with any signs of respiratory depression should be admitted for at least 24 hours of observation. Although limited animal data suggest that saxitoxins adhere to activated charcoal, there are no clinical data to indicate that charcoal hemoperfusion improves clinical outcome.[53]

Chapter 33

CIGUATERA FISH POISONING and CIGUATOXINS

HISTORY

The name ciguatera derives from the Spanish name, "cigua." Spanish immigrants to the Caribbean used cigua to describe an illness associated with the poisonous sea snail *Turbo pica*, which produces a clinical syndrome similar to ciguatera in the Spanish Antilles.[1] Prohibitions on the eating of fish as a means of avoiding ciguatera reportedly date back to Alexander the Great and the T'ang Dynasty (618–907 AD) in China.[2] Although the journal of Captain William Bligh contains a description of symptoms consistent with ciguatera after eating dolphin (mahi-mahi), dolphin is an uncommon source of ciguatera poisoning. More accurate accounts of suspected ciguatera poisoning occurred in the log of the Spanish explorer Pedro de Quiros after eating snapper caught near the New Hebrides (i.e., Vanuatu Islands between Solomon Islands and New Caledonia) in 1606 and in the journal of Captain Cook's botanist after eating a similar fish in the same waters during 1774.[3,4]

EXPOSURE

Source

Ciguatera poisoning occurs following the ingestion of large carnivorous fish, which accumulate ciguatoxins through the food chain. This type of seafood-associated poisoning occurs worldwide as a result both of the migration of affected fish from endemic areas and the transport of affected fish harvested in endemic areas. Benthic dinoflagellates, primarily *Gambierdiscus toxicus* Adachi & Fukuyo, form ciguatoxin precursors (CTX4A) while living in association with bottom-dwelling macro algae attached to dead coral or in the detritus of coral reefs.[5,6] The dinoflagellate, *Ostreopsis lenticularis* Fukuyo, also produces ciguatoxins when grown in cultures with *Pseudomonas* species.[7] Biotransformation and bioaccumulation of these precursors occur as they accumulate in the food chain when carnivorous fish prey on the herbivorous fish that feed on the toxin-containing detritus, algae, or plants.[8] Fish do not appear affected by the presence of ciguatoxins. Weather patterns and natural disasters can destroy coral reefs and increase the concentration of benthic dinoflagellates, such as *Gambierdiscus toxicus* Adachi & Fukuyo, particularly on the windward side of tropical islands. Although scombroid poisoning is the most common seafood-associated illness, ciguatera poisoning is the most common cause of illness resulting from the ingestion of a marine toxin.[9] The most common areas where ciguatoxin is endemic are the western Indian Ocean, Caribbean, and the South Pacific (Solomon Islands, Marshall Islands, Kiribati, Tuvalu, Great Barrier Reef off the coast of Australia).[10] In a study of an outbreak of ciguatera fish poisoning in Hong Kong, fish implicated in the outbreak were coral fish from the South Pacific including brown-marbled grouper, camouflage grouper (*Epinephelus polyphekadion* Bleeker), humphead wrasse or tapiro (*Cheilinus undulatus* Rüppell), leopard coralgrouper (*Plectropomus leopardus*-Lacepède), Russell's snapper or Moses perch (*Lutjanus russelli* Bleeker), and two-spot red snapper (*Lutjanus*

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

bohar Forsskål).[11] A relatively low number of strains of *Gambierdiscus toxicus* produce gambiertoxins, which are biotransformed by marine animals into more polar ciguatoxins; therefore, the distribution of ciguatera poisoning is uneven.[12] Substantial seasonal and yearly variation in ciguatoxin formation occurs as a result of changes in environmental and metabolic conditions, such as increased sea-surface temperature.[13] Consequently, the occurrence of ciguatera poisoning is sporadic and localized to specific areas regardless of the season. Visible blooms of *Gambierdiscus toxicus* are not necessary for the development of sufficient concentrations of ciguatoxins in carnivore fish to produce ciguatera poisoning. In addition, the varying toxin profile for ciguatoxins results in variation in the clinical presentation of ciguatera poisoning between different geographic locations. Although the distribution of ciguatera is worldwide, the areas of highest risk are the subtropical and tropical waters of the Pacific Ocean, Caribbean Sea, and the western Indian Ocean. Figure 33.1 demonstrates in dark shaded areas where there is a moderate to high risk of ciguatoxin in carnivorous fish.

Over 400 species of fish are vectors for ciguatera poisoning,[14] and this type of marine poisoning accounts for more than half of all foodborne outbreaks related to fish in the United States.[15] Table 33.1 lists the most common fish families associated with ciguatera. The fish most commonly involved in ciguatoxin poisoning are reef-dwelling benthic species (e.g., barracuda, grouper, red snapper, parrot fish, surgeon fish, sea bass, mackerel, emperor fish, moray eel, amber jack), which inhabit marine waters between the latitudes of 35 °N and 35 °S (North Carolina to Buenos Aires). The endemic areas of ciguatera in the United States are southern Florida and Hawaii. The shipping of flash frozen food allows the occurrence of ciguatera poisoning in nonendemic areas. Deep sea pelagic fish (e.g., tuna, dolphin, sailfish, marlin, flying fish) do not usually contain clinically significant amounts of ciguatoxins.[16] The most common season for ciguatera poisoning is April through August when the seawater is warm.

Food Processing

Because these toxins are tasteless and odorless, ciguatoxin-contaminated fish do not appear tainted. Consequently, contamination of fish by ciguatoxins is difficult to detect without diagnostic testing. Cooking, salting, drying, smoking, or freezing do not inactivate ciguatoxins; therefore, sufficient quantities of these toxins survive food preparation processes. Unlike marine toxins that are excreted from contaminated organisms (e.g., shellfish), ciguatoxin-contaminated fish remain toxic for long periods of time despite the absence of ciguatoxin in the diet of the affected fish. In a study of 66 specimens of the two-spot red snapper (*Lutjanus bohar* Forsskål) kept in holding ponds for 3–30 months, there was no significant decline in ciguatera toxins at the end of the study periods.[17]

TOXINS

Physiochemical Properties

Ciguatoxins are a family of highly oxygenated, cyclic polyether compounds. Ciguatoxins are acid stable, lipid

soluble, and heat-resistant up to 120 °C (248 °F).[18] Reef-dwelling fish may contain a variety of toxins beside ciguatoxins including maitotoxin, scaritoxin, okadaic acid, prorocentrolide, and palytoxin. In the Pacific Ocean, the main ciguatoxin is Pacific-ciguatoxin-1 (P-CTX-1), which has a molecular weight of 1112 Da and a molecular formula of $C_{60}H_{86}O_{19}$. Figure 33.2 displays the chemical structure of the main ciguatoxin (CTX-1), the precursor (CTX-4B), and five congeners. Maitotoxin-1 is a very large molecule (3422 Da, $C_{160}H_{225}S_2O_{74}$) isolated from cultures of *Gambierdiscus toxicus* Adachi & Fukuyo that is one of the most potent nonprotein toxins (intraperitoneal $LD_{50} \approx 50$ ng/ kg body weight).[19] This toxin is a water-soluble compound that activates voltage-sensitive and receptor-operated calcium channels in the plasma membrane of cells. Ciguatoxins are structurally similar to brevetoxins and yessotoxin.[20] Case reports suggest that ciguatoxins are distributed throughout various body fluids (e.g., breast milk, urine, sperm) as well as across the placenta.[21] Other case reports associated penile pain after ejaculation and the development of dysuria and vaginal discomfort in women following intercourse with men intoxicated with ciguatera.[22,23] Case reports suggest that ciguatoxins are excreted in breast milk, and breastfed infants can develop ciguatera poisoning when breastfed from mothers with ciguatera poisoning.[24,25]

Mechanism of Toxicity

Ciguatoxins prolong the opening of the sodium pores on excitable membranes by activating voltage-dependent sodium channels in muscle cells and nerve cells in small and large myelinated and unmyelinated fibers. Ciguatoxins and brevetoxins bind to site 5 on the neuronal voltage sensitive sodium channels that includes segments S5 of domain IV and S6 of domain I.[26] These sodium channels fail to close, resulting in spontaneous depolarizations, the influx of sodium and water into the cells, and swelling of the nodes of Ranvier. Spontaneous activation of the sodium channels at resting membrane potentials accounts for the neurological effects of ciguatoxin including an acute polyneuropathy, manifest by sensory, small-fiber dysfunction. Pretreatment with tetrodotoxin prevents the ciguatoxin-induced opening of the sodium channel. The role of maitotoxin, scaritoxin, and other polyether compounds in ciguatera intoxication is not well defined. Maitotoxin (CAS RN: 59392-53-9) is a large, complex molecule that affects calcium channels rather than sodium channels;[27] therefore, the pharmacological effects of these two toxins are probably different. However, the low oral toxicity and the limited bioaccumulation of maitotoxin in the food chain limit the contribution of maitotoxin to the etiology of ciguatera fish poisoning.[10] Spectroscopic data of compounds isolated from cultures of marine dinoflagellate *Gambierdiscus toxicus* indicate that scaritoxin is the ciguatoxin congener, ciguatoxin-4A (CTX4A, 52-epiciguatoxin-4B).[5]

DOSE RESPONSE

The clinical response to ciguatoxins depends on the dose, potency of the ciguatoxin, and individual sensitivity. The two main classes of ciguatoxins are the Pacific ciguatoxins and Caribbean ciguatoxins.[28] Differences in

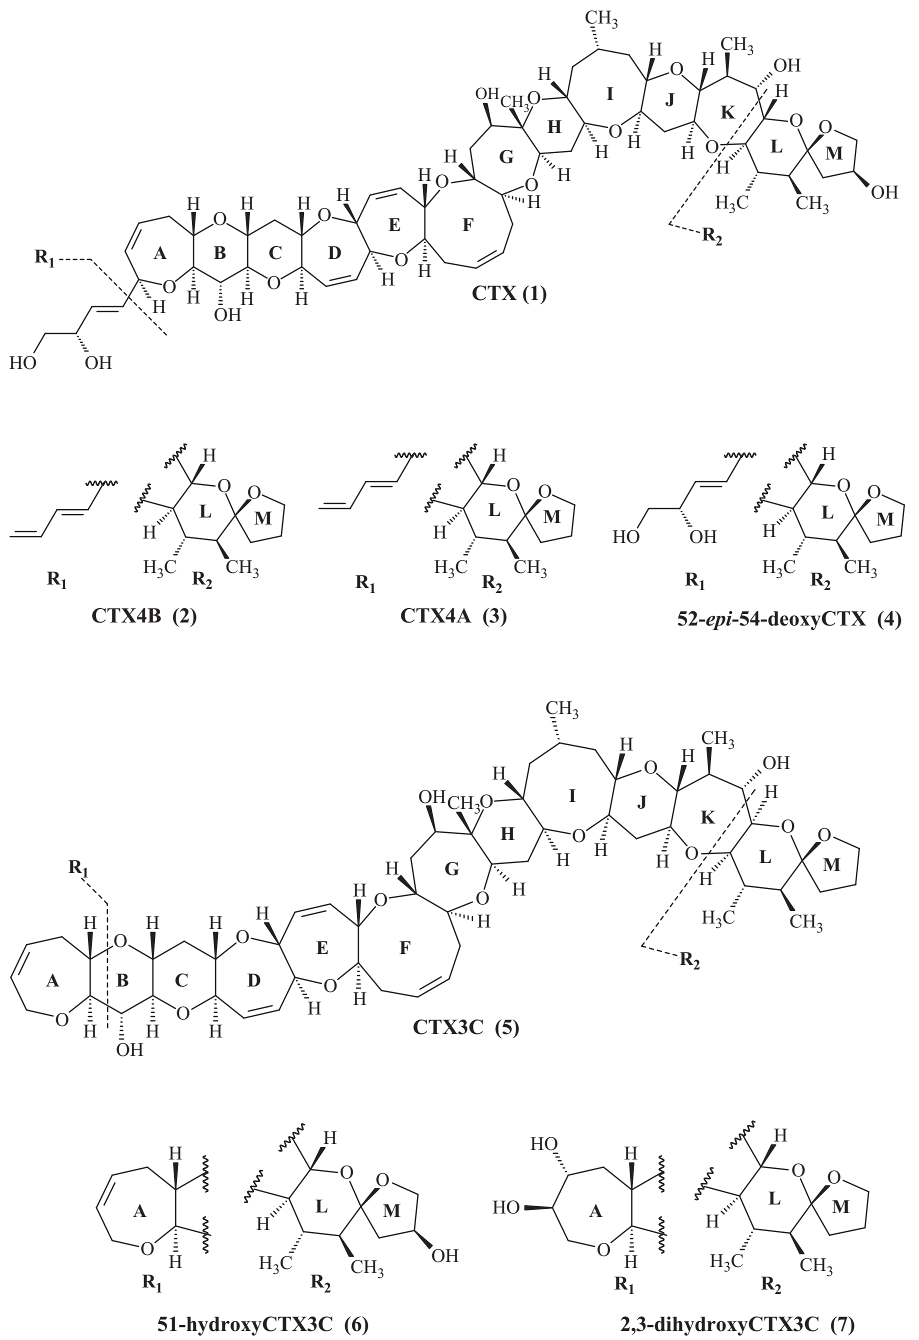

FIGURE 33.2. Ciguatoxin structures. (1) Ciguatoxin (CTX-1, P-CTX-1), (2) ciguatoxin-4B (CTX-4B), (3) ciguatoxin-4A (CTX-4A), (4) 52-epi-54-deoxyCTX, (5) ciguatoxin-3C (CTX-3C), (6) 51-hydroxyCTX3C, and (7) 2,3-dihydroxyCTX3. CTX-4B is the precursor of CTX-1.

the potencies of these two classes of ciguatoxins account for regional variation in the clinical presentation of ciguatera poisoning with Pacific ciguatoxin-1 being about 10 times more potent than Caribbean ciguatoxin-1.[29] Ciguatoxin-1 causes ciguatera poisoning at concentrations as low as 0.1 µg/kg (0.1 ng/g) flesh with a typical range up to approximately 5 µg/kg (5 ng/g) flesh.[30] The ingestion of an estimated 1 kg of coral trout (*Plectropomus maculatus* Bloch) by a 34-year-old man was associated with severe gastrointestinal symptoms, pruritus, anxiety, depression, burning, arthralgias, and lethargy, but his vital signs remained stable.[31] The estimated dose of ciguatoxin by bioassay was 0.25 MU/g flesh (1.3 ng ciguatoxin/g flesh). The estimated safe level for Pacific ciguatoxin-1 (P-CTX-1) in commercial fish is about 0.01 µg/kg (0.01 ng/g) tissue.[32] Mild toxicity probably develops following the ingestion of about 0.05 µg (P-CTX-1) or about 0.001 µg/kg body weight. The severity of ciguatera poisoning depends on several factors including cumulative dose, the profile of ciguatoxins and

associated toxins (maitotoxin, scaritoxin, palytoxin, okadaic acid, brevetoxins), prior exposure, individual susceptibility, and age. For example, neurological symptoms predominate in cases of ciguatera from the Pacific Ocean, whereas gastrointestinal symptoms predominate in cases from the Caribbean Sea.[33] The highest risk of developing ciguatera poisoning is associated with the ingestion of large (>5 pounds) carnivorous fish, particularly the head, visceral organs, eggs, and ovaries of barracuda, grouper, red snapper, sharks, and amberjacks.

CLINICAL RESPONSE

The severity of symptoms and the clinical manifestations of ciguatera are highly variable.[34,35] The classic presentation of ciguatera poisoning is the combination of an early acute gastrointestinal phase (watery diarrhea, nausea, vomiting, abdominal cramps) within 3–6 hours after ingestion of contaminated fish followed by neurological symptoms.[36,37] Typical neurological symptoms include distal and perioral paresthesias, numbness, and cold allodynia (i.e., dysesthesias when touching cold objects). Neurological effects predominate in the Indo-Pacific region, whereas gastrointestinal effects are more prominent in the Caribbean.[28] Table 33.2 lists the most common effects of ciguatera poisoning in a case series of ciguatera poisoning from the Pacific Ocean. The onset of the first symptoms is highly variable with a range of 1 to 48 hours, but the onset of gastrointestinal symptoms more than 24 hours after ingestion of fish indicates that ciguatera poisoning is unlikely. Generalized symptoms include weakness, myalgias, pruritus, arthralgias, dizziness, and a desquamative or erythematous rash. Cardiorespiratory effects develop in a relatively small (<15%) subset of patients with ciguatera poisoning, primarily in patients ingesting large, ciguatoxin-contaminated fish[38] or fish eggs.[39] These effects include hypotension, respiratory insufficiency, and bradycardia in the more severe cases. Occasionally, intermittent hypertension develops. Fatalities occur rarely, primarily from respiratory depression and seizures. The differential diagnosis includes neurotoxic shellfish poisoning, paralytic shellfish poisoning, puffer fish poisoning (tetrodotoxin), botulism, bacteremia, and scombroid fish poisoning. The latter does not cause prominent neurotoxic effects, whereas ciguatera poisoning does not usually produce intense flushing. Although a case report associated transient facial palsy and possible weakness of the hands in a neonate born with ciguatoxin poisoning of the mother at term,[40] no detectable neonatal abnormalities occurred in children born to mothers experiencing ciguatoxin intoxication during their first and second trimesters.[21]

TABLE 33.2. Approximate Frequency of Adverse Effects Associated with Ciguatera Poisoning from Pacific Ocean Fish

Adverse Effect	Occurrence (%)
Extremity paresthesias	89
Circumoral paresthesias	88
Paradoxical dysesthesias	87
Arthralgia	86
Myalgia	85
Diarrhea	73
Asthenia	60
Chills and headache	60
Pruritus	44
Nausea	43
Abdominal pain	42
Vomiting	39
Perspiration	29
Tearing	25
Giddiness	23
Dental pain	21
Neck stiffness	19
Ataxia	15
Dysuria	13
Dyspnea	12
Paresis	10

Gastrointestinal Effects

Gastrointestinal symptoms occur in a majority of patients with ciguatera poisoning. The onset of the gastrointestinal symptoms ranges from minutes to 24 hours after ingestion of ciguatoxin-containing fish with resolution of gastrointestinal symptoms occurring within approximately 12–48 hours. In some cases of ciguatera poisoning, gastrointestinal symptoms do not develop.[10] Animal studies indicate that the diarrhea accompanying ciguatera poisoning does not produce pathological changes in the mucosal lining of the gastrointestinal tract.[41]

Neurological Effects

Neurological symptoms can develop over the first few days after ingestion of ciguatoxin. Prominent neurological symptoms include paresthesias (i.e., abnormal sensations), dysesthesias (i.e., disagreeable sensation following ordinary stimulation), and headache. Paresthesias of the mouth and extremities are classic hallmarks of ciguatera poisoning, and dysesthesias are an early manifestations of the neurological effects of ciguatera. Several reviews indicate that reversal of hot and cold sensation is almost pathognomonic for this toxin, but this symptom (cold allodynia) results more from alteration of sensation

(i.e., cold stimulus producing intense burning and sharp, lancinating pain) rather than cold objects feeling hot.[42] Case reports document painful sensations, such as electric shock, dry ice, burning, or tingling during ciguatera fish poisoning. A case series of 5 patients with ciguatera poisoning did not detect gross alteration of temperature perception, and reversal of hot and cold sensation did not occur during testing.[43] Similar dysesthesias occur during neurotoxic shellfish poisoning.[44] Additional adverse effects associated with ciguatera poisoning include hypersalivation, blurred vision, odontalgia, dysphagia, dysuria, tremor, athetosis, and ataxia.[38,45,46] Typically, ciguatera poisoning is not associated with cognitive changes.[47] Alteration of moods (e.g., depression, anxiety), nightmares, and hallucinations occur occasionally.[48] These latter symptoms should be differentiated from ichthyoallyeinotoxism, which is a rare type of seafood poisoning associated with hallucination and nightmares.[49] In this type of poisoning, symptoms of inebriation, poor coordination, loss of balance, and generalized malaise begin within a few hours of the ingestion of contaminated fish (sea bream, coral grouper, common mullet, convict surgeonfish, rabbitfish, goatfish) followed in a few hours by delirium hallucinations, depression, nightmares, and a sense of impending doom. Patients with ichthyoallyeinotoxism typically recover within 36 hours in contrast to the prolonged course of paresthesias and alteration of sensation associated with ciguatera poisoning.[48]

Sequelae

In a small subset of patients with ciguatera, adverse reactions persist for months to years.[50,51] These symptoms include protracted pruritus, fatigue, postural lightheadedness, arthralgias, and paresthesias. Certain foods (e.g., fish, chicken, pork, peanuts), ethanol consumption, heavy exercise, and periods of stress are associated with exacerbation of these chronic symptoms.[52] These sensitivities can persist long after the initial symptoms resolved. Ciguatera poisoning does not confer immunity to subsequent attacks, and subsequent attacks are often more severe than the original attack.[6] There are few data on the effect of ciguatoxin on the fetus. The occurrence of ciguatera poisoning in the first and second trimester of pregnancy was not associated with abnormal fetal development, and both infants were born full-term with APGAR scores of 9 (1 minute) and 9 (5 minutes).[31,53] Two days before expected birth, a term mother developed severe ciguatera poisoning.[54] She experienced tumultuous and bizarre fetal movements that resolved within 36 hours. Fetal heart monitoring did not reveal any abnormalities, but she subsequently delivered via Caesarean section a 3.8 kg male neonate with left-sided facial palsy. Examination the following day suggested some possible myotonia of the small muscles of the hands of the neonate. At 6 weeks of age, the child appeared normal with the exception that he had not smiled.

DIAGNOSTIC TESTING

Analytical Methods

Ciguatera poisoning is a clinical diagnosis based on the recent consumption of fish known to cause ciguatera along with the abrupt onset of gastrointestinal and neurological symptoms consistent with ciguatera poisoning. The most common method for the confirmation of ciguatoxins in fish is the mouse bioassay. *In vivo* testing with bioassays involves the oral dosing of flesh or the intraperitoneal injection of crude extracts of fish into mice. The detection of ciguatoxins is complicated because of a number of factors including multiple structural forms, low concentrations associated with ciguatera, and the difficulty synthesizing fragments of the basic structure of ciguatoxins.[55] There are no well-validated analytical methods for the rapid detection of ciguatoxins in human blood and urine samples. Immunoassays are complicated by the structural similarity of low-potency ciguatoxins, which cross-react with the antibodies to P-CTX-1; however, some immunoassays are available commercially (e.g., immunobead assay, Cigua-Check™, Oceanit Test Systems, Honolulu, HI).[56] Typically, these immunoassays do not detect ciguatoxin concentrations <0.05 μg/kg fish, and some false-positive reactions occur as a result of nonspecific binding.[29] Gradient reversed phase highperformance liquid chromatography/tandem mass spectrometry allows detection of Pacific ciguatoxin-1 (P-CTX-1) in the sub-ppb concentration of samples of fish flesh.[57]

Abnormalities

There are no characteristic laboratory abnormalities associated with ciguatera poisoning. The complete blood count, creatine kinase, and electrocardiogram are usually normal.[58] In cases with severe gastrointestinal symptoms, laboratory evidence of electrolyte imbalance and dehydration can occur. Reversible T-wave changes can develop during ciguatera poisoning, but myocardial injury does not usually occur. Severe cases of ciguatera poisoning are associated with slowing of sensory conduction velocity, prolongation of the absolute refractory period, and increased relative refractory period.[59] However, electrophysiological studies are usually normal in most cases of ciguatera poisoning with the exception of normocalcemic latent tetany manifest by

doublets, triplets, and multiplets with relative electrical silence between groups of discharges.[60]

TREATMENT

Treatment for ciguatera poisoning primarily is supportive. Patients with severe gastrointestinal symptoms may require fluid and electrolyte replacement for dehydration. Bradycardia typically responds to atropine, and hypotension is treated with fluids and vasopressors as needed.

Decontamination

Decontamination measures are not usually necessary because of the delay between the ingestion of contaminated fish and the onset of symptoms. There are no clinical data to determine if the use of activated charcoal improves the outcome of ciguatera poisoning.

Antidotes

There are no antidotes for ciguatera, and most patients require only supportive treatment. Case reports suggest that the intravenous administration of 20% mannitol reduces some of the symptoms associated with ciguatera poisoning, particularly when administered within 24–48 hours of ingestion.[61] However, there is a lack of randomized clinical trials to support the efficacy of mannitol for the treatment of ciguatera poisoning. A double-blind randomized clinical trial comparing mannitol infusions with normal saline in 50 patients with sensory paresthesias from ciguatera poisoning did not demonstrate a difference in symptoms between the two groups at 24 hours after therapy.[62]

The usual intravenous mannitol dose for ciguatera poisoning is 10 mL 20% mannitol (1 g)/kg body weight over 30–45 minutes. Patients receiving mannitol should be well hydrated to correct any pre-existing fluid or electrolyte imbalances. A second dose of 5 mL 20% mannitol (0.5 g)/kg body weight can be repeated in 3–4 hours if symptoms do not improve. The lack of a response to two infusions indicates that further use of mannitol probably would not be efficacious. Mannitol infusions do not usually resolve all symptoms of ciguatera poisoning. Although serious complications of a mannitol infusion are unusual in well-hydrated patients, adverse effects include pain at the infusion site and thrombophlebitis.[63]

Supplemental Care

Symptomatic treatment includes the use of antiemetics (prochlorperazine, metoclopramide), antidiarrheal agents, and antipruritics (H_1 and H_2 histamine blockers). There are inadequate clinical data to determine if the use of antiemetics or antidiarrheal agents exacerbates the course of ciguatera poisoning. The bradycardia associated with ciguatera usually responds to atropine, if needed to support blood pressure.[64] Hospitalization is appropriate for those patients with significant volume depletion or those who are severely symptomatic after initial treatment. Unproven therapies for the treatment of persistent dysesthesias and pruritus include amitriptyline (25 mg twice dai1y),[65,66] tocainide, and gabapentin (400 mg orally t.i.d.).[67] There are inadequate data to support the use of calcium gluconate or corticosteroids during ciguatera intoxication.[42]

Chapter 34

PUFFER FISH POISONING and TETRODOTOXIN

HISTORY

The hieroglyphics of ancient Egypt contain references to puffer fish dating back to 2700 BC. Ancient Chinese literature also contains references to the dangers of eating puffer fish. The highest number of fatalities from the consumption of puffer fish occurs in Japan where puffer fish (fugu) is a traditional delicacy. The poems of the Edo era (17th–19th centuries) indicate that fugu was a popular food during this period. In Japan, the oldest record of puffer poisoning occurred in the Nara and Heian eras (200 AD).[1] The log of Captain Cook, written in September, 1774 off New Caledonia, contains a description of a puffer fish as well as weakness and paresthesias that resulted from the ingestion of the roe and liver of this fish.[2,3] Although a crude extract of puffer fish containing tetrodotoxin was isolated in 1909, the structure of tetrodotoxin was not elucidated until 1964.[4,5]

The administration of tetrodotoxin can cause the "locked-in" syndrome characterized by complete flaccidity with retention of consciousness. Investigation into zombies associated with Haitian voodoo culture suggests that the pharmacological agents used in these rituals contain ingredients from one or more species of tetrodotoxin-containing puffer fish (*Diodon hystrix* L., *Diodon holacanthus* L., *Sphoeroides testudineus* L.).[6] Gas chromatography/mass spectrometry and liquid chromatography/mass spectrometry analysis of a powder used by Haitian voodoo sorcerers demonstrated the presence of an alkaline degradation product of tetrodotoxin (2-amino-6-hydroxymethyl-8-hydroxyquinazoline) after base treatment.[7] Direct thermospray mass spectral activity detected tetrodotoxin and an isomer.

EXPOSURE

Source

Puffer fish belong to the Tetraodontidae family (blowfish, globefish, puffer, rabbitfish, swellfish, toadfish, sharp-nosed puffer) of the order Tetraodontiformes, which is distributed worldwide. Tetrodotoxin-containing puffer fish occur primarily in Japan and the Indo-Pacific Oceans. Although puffer fish near Japanese waters contain primarily tetrodotoxin, puffer fish from other locations contain saxitoxins. Puffer fish in southern Florida contain a sufficient amount of saxitoxin to produce symptoms consistent with paralytic shell fish poisoning.[8] Other families in the order Tetraodontiformes also contain tetrodotoxin including Balistidae (filefish, triggerfish), Molidae (ocean sunfish), Ostraciidae (boxfish), and Diodontidae (porcupine fish).[9] Puffer fish inhabit shallow waters of the temperate and tropical zones, and specimens range in size from 25 to 30 cm (10–12 inches). In addition to puffer fish, a variety of marine and terrestrial animals contain tetrodotoxin as listed in Table 34.1. The source of tetrodotoxin remains controversial. Certain bacteria (e.g., *Microbacterium arabinogalactanolyticum, Serratia marcescens, Vibrio alginolyticus, Vibrio fischeri*) and the actinomycete *Nocardiopsis dassonvillei* can produce tetrodotoxin.[10–12]

TABLE 34.1. Presence of Tetrodotoxin in the Animal Kingdom

Phylum	Class	Family/Subfamily	Common Name
Chordata	Amphibia	Salamandridae	Newts
		Bufonidae	Atelopid Frogs
Chordata	Osteichthyes (Pisces)	Tetraodontidae	Blowfish, globefish, puffers, rabbitfish, swellfish, toadfish, sharp-backed puffers
		Diodontidae	burrfish, porcupine fish
		Gobiidae	yellowfin toxic goby
Mollusca	Gastropoda	Buccinidae, Bursidae, Terebridae, etc.	Marine snails
	Cephalopoda	Octopodidae	Blue-ringed octopus
Echinodermata	Asteroidea	Astropectinidae	Starfish
Arthropoda	Crustacea	Xanthidae	Crabs

Source: From Ref 9.

Salamanders, such as the California newt and the eastern salamander (*Ambystoma punctatum*), contain sufficient quantities of tetrodotoxin to cause death following ingestion.[13] Other species that contain tetrodotoxin include the yellowfin toxic goby [*Yongeichthys criniger* (Valenciennes in Cuvier and Valenciennes)], *Atelopus* frogs of Costa Rica, and the blue-ringed octopus (*Hapalochlaena maculosa*) as well as the ivory shell, the trumpet shell (*Charonia sauliae* Reeve), and gastropod mollusks (*Nassarius* spp., *Natica* spp.).[14,15] Seasonal and geographic variation occurs in the concentration of tetrodotoxin within puffer fish specimens. A study of two puffer fish species (*Takifugu niphobles* Jordan and Synder, *Takifugu alboplumbeus* Richard) in coastal waters near Hong Kong demonstrated moderate toxicity (100–1000 MU [mouse unit]) in the ovaries of both species and the liver of *T. niphobles* during non-spawning seasons.[16] The intestines and skin were weakly toxic (10–100 MU), whereas the flesh was not toxic (<10 MU) during the entire year. Contrary to popular belief, these two species were relatively less toxic during the spawning season. Accumulation of tetrodotoxin in the puffer fish does not alter the behavior of the puffer fish because of a mutation in the protein sequence of their sodium channels that results in insensitivity to the effects of tetrodotoxin.[17]

Food Processing

The Japanese puffer fish (fugu) is a delicacy in Japan, particularly tora-fugu (*Sphoeroides rubripes* Temminck & Schlegel) and ma-fugu (*Tetraodon porphyreus* Temminck & Schlegel). Specially licensed chefs in fugu restaurants prepare the puffer fish as thinly sliced "sashimi" fillets of muscle that contain only enough tetrodotoxin to cause mild perioral tingling and euphoria. Some gourmets prefer the liver ("kimo"), which can be highly toxic. Most cases of tetrodotoxin poisoning result from the ingestion of fish dishes prepared by inexperienced chefs. Tetrodotoxin is heat stable, and cooking does not inactivate this toxin. Although the importation of fugu into the United States is illegal, the smuggling of prepackaged fugu from Japan was associated with puffer fish poisoning that resolved without sequelae within one day.[18] US customs agents have also interdicted packages of fugu during attempted entry into the United States.[19]

TOXINS

Physiochemical Properties

Tetrodotoxin (CAS RN:4368-28-9) is the most potent marine nonprotein toxin with the exception of palytoxin and maitotoxin.[20] The molecular formula of tetrodotoxin is $C_{11}H_{17}N_3O_8$ and the molecular weight is 319.3 Da. Figure 34.1 demonstrates the chemical structure of tetrodotoxin. Analogues of tetrodotoxin present in puffer fish include 11-*nor*tetrodotoxin-6(R)-ol and other tetrodotoxin derivatives.[21] This highly polar, guanidine-substituted polysaccharide is soluble in acidic aqueous solutions, but is only slightly soluble in water and insoluble in most organic solvents. Strongly acidic or alkaline solutions deactivate tetrodotoxin. The distribution of this nonprotein, heat-stable neurotoxin within and between specimens of puffer fish is not uniform.[22] The highest concentrations of tetrodotoxin occur in the liver, roe, gonads, and skin. In a study of the Japanese marine puffer (*Chelonodon patoca* Hamilton, okinawafugu), all specimens contained tetrodotoxin.[23] For the specimens collected, the tetrodotoxin concentrations in various organs were as follows: skin, 60–6,700 MU/g; ovary, 25–670 MU/g; testes, 45–550 MU/g; muscle 2–390 MU/g; and liver, 5–380 MU/g. There is also substantial seasonal variability in tetrodotoxin concentrations in the same organs. Tetrodotoxin-producing strains of bacteria are

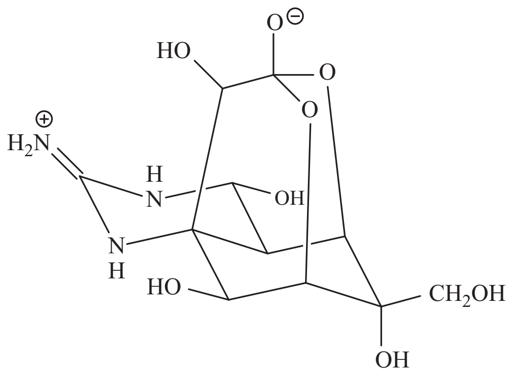

FIGURE 34.1. Chemical structure of tetrodotoxin.

present in the intestines of puffer fish, primarily from the family Vibrionaceae [e.g., *Beneckea alginolytica* (Miyamoto et al.) Baumann et al.].[24]

Mechanism of Toxicity

Tetrodotoxin blocks the voltage-gated sodium channel at the same site as saxitoxin. In contrast to most other fish toxins, which alter the sodium channel by binding to domains I–VI of the α-subunits of the sodium channel, tetrodotoxin occludes the outer pore of the sodium channel.[25] This marine toxin blocks tetrodotoxin-sensitive subtypes of the sodium channel in the single nanomolar range, particularly those neurons associated with peripheral nerve excitability.[26] Tetrodotoxin disrupts sodium conductance by stoichiometrically (i.e., one tetrodotoxin molecule to one sodium channel) blocking the fast sodium channel during cell depolarization, resulting in a competitively reversible block at the motor end plate. During severe intoxication impulse conduction ceases. Tetrodotoxin is slightly less neuroactive than saxitoxin, but its effects are more prolonged. Saxitoxin produces less hypotension and vomiting than tetrodotoxin.[22] Experimental reversal of the motor end plate blockade occurs when anticholinergic drugs increase the release of acetylcholine at the neuromuscular junction. This toxin affects the myelin sheaths, where selective blockade of voltage-gated sodium channels at the nodes of Ranvier inhibit motor and sensory conduction by reducing the generation of action potentials and impulse conduction. The axons are spared. Tetrodotoxin does not cross the blood–brain barrier; therefore, consciousness typically remains intact during the peripheral blockade of neurologic function.

DOSE RESPONSE

The effect of tetrodotoxin depends on the amount ingested, age, and pre-existing conditions. The estimated minimum lethal oral dose of tetrodotoxin is approximately 2 mg (10,000 MU equivalents). The threshold for toxicity is not well defined, but the threshold probably is near the minimum lethal dose.

CLINICAL RESPONSE

Toxicity from puffer fish results from ingestion of tetrodotoxin-containing tissues rather than envenomation by contact with dorsal spines. Most individuals ingesting tetrodotoxin-contaminated puffer fish develop no symptoms or mild perioral paresthesias, lightheadedness, and nausea that do not progress to weakness or paralysis. Numbness of the tongue and lips begin soon (i.e., 15 minutes to a few hours) after ingestion of the puffer fish. Occasionally, symptoms are delayed 3–6 hours. More rapid onset of symptoms, particularly weakness, suggests more severe poisonings, and symptoms usually begin within 1–2 hours during severe puffer fish poisoning. The paresthesias progress to involve the face and extremities along with sensations of floating, lightheadedness, and headache. Other neurological symptoms include blurred vision, vertigo, and diffuse paresthesias.[27] Gastrointestinal symptoms are variable with nausea, vomiting, and abdominal pain being the most common symptoms. Diarrhea is uncommon.

In more severe cases, an ascending paralysis progresses rapidly and cardiorespiratory dysfunction develops as outlined in Table 34.2.[28] Hypotension, bradycardia, depressed corneal reflexes, and fixed, dilated pupils indicate a serious poisoning. An ascending paralysis develops within 6–24 hours after ingestion, manifested by weakness, loss of coordination, cranial nerve dysfunction, and hyporeflexia. Despite the presence of complete paralysis, the patient usually remains lucid until cardiopulmonary instability develops. Death usually occurs during this period; however, the prognosis for recovery is good if the patient survives >24 hours after ingestion of the puffer fish. Cardiac abnormalities include dysrhythmias (bradycardia, tachycardia, depressed AV node conduction) and hypotension. Severe hypertension can complicate puffer fish poisoning, particularly in patients with pre-existing hypertensive disease.[29] Dermatological changes associated with puffer fish poisoning include petechiae, vesicles, and exfoliative dermatitis.[36] Tolerance does not develop following repeated exposure to tetrodotoxin.

DIAGNOSTIC TESTING

Analytical Methods

Bioassays determine the semi-quantitative concentration of tetrodotoxin based on the mouse units (MU).

TABLE 34.2. Progressive Stages of Tetrodotoxin Poisoning

Stage	Neurological	Gastrointestinal	Cardiorespiratory
First	Paresthesias (lips, tongue, throat), taste disturbances, dizziness, headache, diaphoresis, miosis	Nausea, vomiting, diarrhea, abdominal pain, drooling	
Second	Progressive neuromuscular symptoms (diffuse paresthesias, weakness/paresis of digits/extremities, hyporeflexia, mydriasis		
Third	Profound neuromuscular symptoms (dysarthria, dysphagia, cranial nerve palsies, ataxia, loss of coordination, ascending paralysis of extremities		Hypotension, hypertension, bradycardia, tachycardia, AV nodal block, dyspnea, cyanosis
Fourth	Seizure, altered mental status, complete paralysis, areflexia, fixed/dilated pupils		Respiratory failure, shock

Source: Adapted from Ref 28.

One MU is equivalent to the amount of toxin required to kill 20g-ICR strain male mice in 30 minutes after a single intraperitoneal injection. One MU corresponds to approximately 0.2 μg tetrodotoxin. Specific methods for the detection of tetrodotoxin include affinity chromatography, mass spectrometry of tetrodotoxin after alkaline degradation to the C9 derivative, and high performance liquid chromatography (HPLC) with post-column derivatization and fluorescence detection after clean up by solid-phase extraction cartridges.[30] The limit of quantitation for tetrodotoxin with the latter technique is approximately 5 ng/mL and 20 mg/mL for serum and urine samples, respectively.

Biomarkers

The serum concentrations of tetrodotoxin fall rapidly within 12–24 hours after ingestion of contaminated food. Case reports suggest that the elimination of tetrodotoxin from plasma is rapid (<24 hours), whereas tetrodotoxin remains detectable in urine samples for at least 4 days during severe tetrodotoxin poisoning as measured by gas chromatography.[31] A serum tetrodotoxin concentration of 36 ng/mL was associated with coma, bradycardia, hypotension, flaccid paralysis, and respiratory failure. The serum tetrodotoxin concentration was not detectable the following day despite profound weakness and stable cardiorespiratory status. Postmortem examination of fatal cases of puffer fish poisoning suggest that the concentrations of tetrodotoxin in the stomach and intestines are relatively low during postmortem examination of patients dying from puffer fish poisoning.[32]

Abnormalities

During the first 3 days of severe puffer fish poisoning manifest by coma, respiratory failure, and hypotension, nerve conduction studies demonstrated reduction or absence of conduction velocities and amplitudes of complex muscle (CMAPs) and sensory nerve action potentials (SNAPs).[31] Insertional activity is typically normal. The slowed conduction and reduced amplitudes are more profound in sensory nerves rather than motor nerves.[33] The F waves (proximal motor latencies) are also prolonged. These abnormalities resolved following clinical improvement within 5 days.[34] These changes in amplitude and conduction velocity are nonspecific indicators of nerve impairment. Laboratory abnormalities during severe tetrodotoxin poisoning include leucocytosis and respiratory acidosis.[35] Occasionally, serum creatine kinase concentrations are slightly elevated, but the MB fraction is usually normal in the absence of myocardial ischemia.[36]

TREATMENT

Treatment is primarily supportive. Patients should be evaluated for evidence of hypotension, shock, respiratory depression, and dysrhythmias with cardiac monitoring, electrocardiogram, and pulse oximetry. The presence of hypotension requires the use of intravenous fluids and inotropic agents (i.e., alpha agonists) as needed. The respiratory status should be carefully monitored for the development of progressive respiratory insufficiency, and assisted ventilation and supplemental oxygen should be initiated if respiratory failure develops. Fluid and electrolytes should be replaced as indicated by laboratory testing and physical examination. Bradycardia and hypotension in a patient suffering from mild intoxication usually respond to atropine, intravenous fluids, and oxygen. There are inadequate clinical data on the efficacy of activated charcoal. There are no antidotes. All patients with suspected puffer fish poisoning should be admitted for observation.

Based on case reports and theoretical considerations, the response of muscle weakness to the intravenous use of anticholinesterase drugs (e.g., 10 mg edrophonium) is equivocal.[37] A case report suggested some improvement in muscle strength after the intravenous administration of 10 mg edrophonium,[38] but the patient remained intubated for one more day. Another case report demonstrated no obvious improvement in neurological symptoms associated with tetrodotoxin poisoning after the intravenous administration of 0.05 mg neostigmine/kg.[39] There are no data to support the use of corticosteroids or antihistamines.

Chapter 35

RED WHELK and TETRAMINE

HISTORY

Tetramine has been recognized as a cause of food poisoning following the ingestion of whelks since the 1950s. The appearance of an intense, self-limited illness manifest by severe headache, malaise, nausea, vomiting, lightheadedness, and urticaria was associated with the consumption of specimens of *Neptunea arthritica* Bernardi from the northern seas of Japan and *Neptunea intersculpta* Sowerby from the Japan Sea. Asano et al confirmed tetramine as the main toxic compound in the salivary glands of *Neptunea arthritica* Bernardi.[1] In the 1950s, Fange and colleagues confirmed the presence of tetramine in the salivary glands of *Neptunea antiqua* L. from Norwegian coastal waters.[2] Case reports of red whelk poisoning appeared in Scotland in the 1970s.[3]

EXPOSURE

Source

In the United Kingdom, food poisoning occurs when red whelks (*Neptunea antiqua* L.) are consumed instead of the edible whelk (*Buccinum undatum* L.). Red whelks have a large shell that is pale yellow to orange with no ridges compared with the smaller, smooth shell of the edible whelk. Several members of the Buccinidae family of gastropod mollusks contain the autonomic ganglionic agent, tetramine, in their salivary glands including *Buccinum leucostoma* Lischke, *Neptunea antiqua* L., *Neptunea arthritica* Bernardi, *Neptunea intersculpta* Sowerby, and *Neptunea lyrata* Martyn.[1,4] *Neptunea antiqua* is a necrophagous scavenger that inhabits the cold temperate waters of the Eastern Atlantic from the Bay of Biscay to the Arctic regions. The Oregon triton (*Fusitriton oregonensis* Redfield) from the Ranellidae family of gastropods also contains tetramine. Red whelks normally inhabit depths in the ocean up to 100–200 meters (325–650 feet), and persons collecting shellfish near the coastline do not usually encounter this marine gastropod. Although marine gastropods are associated with red whelk poisoning, tetramine occurs as metabolites in at least three marine phyla (Cnidaria, Mollusca, and Bryozoa), which include sea anemones (*Metridium dianthus* Ellis, *Actinia equina* L.), Portuguese man-of-war (*Physalia physalis* L.), hydroids (*Hydra littoralis* Hyman), giant Caribbean anemone (*Condylactis gigantea* Weinland), soft coral (*Plexaura flexosa* Lamouroux), and marine bryozoans (*Cellaria fistulosa* L., *Cellaria sinuosa* Hassall). Some plants (e.g., Sudanese *Courbonia virgata* Brongn.) also contain tetramine.

Food Processing

Although most of the tetramine occurs in the salivary glands of buccinid gastropods, other tissues can contain small amounts of tetramine as a result of the diffusion of tetramine from the salivary glands. Tetramine also diffuses into the broth during the boiling of tetramine-containing, marine gastropods. However, removing the contents of these marine gastropods and broiling does not prevent toxicity.[3] Broiling contaminated gastropods for 15 minutes reduces the mean tetramine content in the tissue by approximately 30%.[5] The heating of specimens of *Neptunea arthritica* and *N. intersculpta* to 100 °C (212 °F) for 5 minutes reduced the tetramine content by

40 to 50% as measured by ion chromatography with a detection limit of 5 µg/mL.[6]

TOXINS

Physiochemical Properties

The red whelk contains the heat stable toxin, tetramine (CAS No. 3810-53-5), in their salivary glands. The molecular formula of this simple quaternary ammonium compound (tetramethylammonium ion) is $C_4H_{12}N^+$. This compound should not be confused with tetramethylenedisulfotetramine (CAS No. 80-12-6), which is a potent rodenticide that produces status epilepticus via non-competitive γ-aminobutyric acid (GABA) antagonism. Both these compounds have the common name, tetramine.[7] Although originally isolated as tetramethylammonium hydroxide from a sea anemone, the hydroxide salt is too basic to exist in nature.[8] In samples of salivary glands from four specimens of *Neptunea arthritica*, the tetramine concentration ranged from 8.4–12 mg/g tissue, whereas three samples of salivary glands from *Neptunea polycostata* Scarlato contained 0.85–4.9 mg/g tissue.[15] The tetramine concentration in muscle samples from these two species ranged from 0.016–0.18 mg/g tissue and 0.003–0.007 mg/g tissue, respectively. The tetramine concentration in salivary glands from *Fusitriton oregonensis* Redfield ranged from about 3–4 mg/g gland.[2] In addition to the significant variation in tetramine content between individual specimens, a study of salivary glands of *Neptunea antiqua* from the central western Irish Sea indicated that substantial seasonal variation in tetramine content occurred in the salivary glands.[9] The tetramine concentration ranged from undetectable to 6.53 mg/g gland during the season with the highest concentration after the breeding in July. Similar tetramine concentrations occurred in buccinid gastropods analyzed in specimens obtained from Japanese waters. The salivary glands from nine specimens of *Neptunea intersculpta* harvested during September contained 4.5–27 mg tetramine.[10] Two samples of salivary glands from *N. arthritica* obtained in November contained 1.8 mg and 12 mg tetramine. Tetramine was present in most samples of meat from *N. intersculpta*, but the total tetramine content typically was <1–2 mg. In experimental studies of rats, the elimination of tetramine is rapid ($t_{1/2} \approx 1$ hour) with most elimination occurring via the renal excretion of unchanged tetramine.[11]

Mechanism of Toxicity

The salivary glands of these marine gastropods empty into the mouth, and there is no venom apparatus for the rapid injection of tetramine. Tetramine blocks nicotinic acetylcholine receptors, which produces a complete blockade of neuromuscular transmission in experimental studies similar to conotoxins associated with cone shells. Other toxins (e.g., inhibitors of neuronal calcium channels) also may occur in the salivary glands of red whelk, but the effects of these toxins are unclear.[9]

DOSE RESPONSE

The consumption of red whelk containing 3.75 mg tetramine/100 g tissue (i.e., total estimated dose 1.75–2.5 mg) was associated with red whelk poisoning.[12] The estimated oral lethal dose of tetramine based on animal studies is 250–1000 mg.[13] However, there are no human data because of the lack of reported fatalities associated with red whelk poisoning.

CLINICAL RESPONSE

The clinical presentation of red whelk poisoning is similar to mild nicotine intoxication.[8] Symptoms of red whelk poisoning involve the gastrointestinal and neurological systems, usually within 30 minutes to 1 hour of the consumption of these gastropods. Case reports associated nausea, vomiting, diarrhea, paresthesias, diplopia, blurred vision, vertigo, headache, weakness, and ataxia with the consumption of red whelk.[12] Typically, symptoms resolve within 3–24 hours because of the rapid elimination of tetramine from the blood. Deaths are not usually associated with red whelk poisoning.

DIAGNOSTIC TESTING

Bioassays based on the dose-lethal time curves for mice are the most common method for determining the presence of toxins in tetramine-containing gastropods.[14] More specific and sensitive methods for the quantitation of tetramine include capillary zone electrophoresis/tandem mass spectrometry and the combination of liquid chromatography for separation and electrospray ionization-single quadrupole mass spectrometry for detection.[15]

TREATMENT

Treatment is supportive. There are no antidotes. There are inadequate human data on red whelk poisoning to recommend specific treatment.

Chapter 36

SCOMBROID FISH, SCOMBROTOXIN, and HISTAMINE

HISTORY

The first recorded episode of scombroid fish poisoning involved the consumption of bonito by British sailors aboard the *Triton of Leith* during 1828.[1] In Japan, scombroid fish poisoning was a major cause of food-related illness during the 1950s.[2] The first recorded episode of scombroid fish poisoning in the United States occurred in the late 1960s. During the late 1970s, scombroid fish poisoning was recognized as a cause of seafood-related illness in the United Kingdom.[3]

EXPOSURE

Source

Worldwide, scombroid poisoning is the most common cause of illness related to the ingestion of seafood. The ingestion of freshwater fish does not usually cause scombroid fish poisoning. Deep-water fish from the Scombridae (tuna, bonito, mackerel, albacore) and Scomberesocidae (saury) families have high concentrations of the free amino acid, histidine, in their dark meat. The term scombroid fish poisoning is a misnomer because a variety of nonscombroid fish also cause scombroid fish poisoning including amberjack, mahi-mahi (bonito), bluefish, marlin, sockeye salmon, herring, pilchards, sardines, and anchovies. Inadequate refrigeration after these fish are caught results in the growth of bacteria, which synthesize histamine by the enzymatic action of histidine decarboxylase on histidine. A variety of bacteria produce histidine decarboxylase including *Proteus vulgaris, Escherichia coli, Morganella morganii, Clostridium* spp., *Salmonella* spp., *Enterobacter aerogenes, Klebsiella pneumoniae, Proteus mirabilis, Vibrio alginolyticus, Aeromonas spp., Serratia fonticola, Acinetobacter spp.,* and *Hafnia alvei*.[4] *Lactobacillus buchneri* is associated with histamine formation in cheese.[5] The rate of histidine decarboxylation varies between bacterial species.[6] Therefore, some species are more important histamine producers (e.g., *Hafnia alvei*) than others (e.g., *Morganella morganii*). Additionally, many bacteria produce enzymes that convert lysine to cadaverine, ornithine to putrescine, and arginine to spermidine and spermine. Consequently, the formation of histamine depends on several variables including the number and type of bacterial species, the fish species, the part sampled, time after catch, and temperature. Biogenic amines (i.e., histamine, cadaverine, tyramine, putrescine) also occur in meat and meat products, fruits, vegetables, cheese, sauerkraut, wine, beer, and soy sauce.[7,8]

Food Processing

Once formed, food processing (e.g., freezing, smoking, cooking, canning) does not inactivate the causative toxins associated with scombroid fish poisoning. Rapid cooling of fish after catching and the maintenance of adequate refrigeration during handling and storage substantially reduces the risk of scombroid fish poisoning. Histamine formation is minimal at temperatures below 0 °C (32 °F), but some bacteria can produce histamine in fish at temperatures between 0 °C (32 °F) and 10 °C

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

(50 °F).[9] Refrigeration usually reduces the formation of histamine by enteric bacteria that produce histamine decarboxylase. An *in vitro* study indicated that the lower limit for production of toxicologically significant concentrations of histamine in tuna broth for *E. coli* and *K. pneumoniae* was 30 °C (86 °F) and 7 °C (45 °F), respectively.[10] Prolonged drying reduces histamine content, but freezing, smoking, and cooking do not destroy preformed histamine or prevent scombroid poisoning. Histamine production in smoked fish usually occurs prior to smoking. Although smoking probably reduces the histamine concentration in contaminated fish, storing the smoked fish at room temperature increases bacterial activity and histamine formation. In a study of 33 samples from retail smoked fish, storage for 2 days at room temperature resulted in histamine concentrations exceeding 200 ppm in four samples with a range up to about 1650 ppm.[11] An outbreak of scombroid fish poisoning occurred after the consumption of contaminated fish when allowed to stand for 3–4 hours at room temperature, but ingestion of the same fish allowed to stand 1 hour at room temperature did not cause illness.[12]

TOXINS

Physiochemical Properties

The toxin or toxins associated with scombroid fish poisoning are usually tasteless, odorless, and heat stable. Some heavily contaminated fish have a peppery or bitter taste. In humans, L-histidine ammonia lyase catalyzes the conversion of histamine to urocanic acid. Further biotransformation produces glutamate and α-ketoglutarate, which enters the citric acid cycle. The presence of diamine oxidase (histaminase) and histamine methyl transferase in the intestinal tract detoxify histamine prior to gastrointestinal absorption. Some medications, such as monoamine oxidase inhibitors, increase the severity or prolong the course of scombroid poisoning by inhibiting the metabolism of histamine.[13] Spoiling fish accumulate cadaverine and/or putrescine with the former being present in higher concentrations than histamine. However, fish that accumulate these biogenic amines are not known to be toxic when histamine concentrations are low.[16] In a study of 8 volunteers ingesting 90 mg histamine, histamine concentrations in plasma samples remained elevated above baseline concentrations for at least 24 hours after ingestion.[14]

Mechanism of Toxicity

The mechanism causing scombroid fish poisoning is complex and incompletely elucidated. Volunteer studies indicate that endogenous histamine, but not dietary (exogenous) histamine, is a major determinant of scombrotoxicosis.[15] Although histamine is an important part of scombroid fish poisoning, additional factors probably contribute to the development of this illness because histamine consumed in spoiled fish is more toxic than oral histamine.[16] The majority of 440 suspected incidents of scombroid fish poisoning in the United States between 1976 and 1990 were associated with the ingestion of fish that contained histamine concentration considered safe for consumption (i.e., <5 mg/100 g flesh).[17] The administration of oral histamine (e.g., 100 mg) far exceeding histamine doses associated with scombroid fish poisoning does not produce this illness. There are three types of histamine receptors (H_1, H_2, H_3), which produce a variety of effects including dilation of peripheral blood vessels resulting in hypotension, headaches, erythema, and urticaria. Although dysrhythmias are not a prominent feature of scombroid fish poisoning, potential arrhythmogenic actions of histamine receptors include H_1 receptor-mediated slowing of atrioventricular conduction and H_2-receptor-mediated increase in sinus and ventricular automaticity. Additional effects include nausea, vomiting, diarrhea, abdominal cramps, pruritus, and peripheral pain.

The exact chemical nature of scombrotoxin is not known. Potential mechanisms of toxicity include the facilitation of histamine absorption, the reduction of histamine absorption or decreased histamine metabolism, and the potentiation of histamine toxicity by other biogenic amines. However, in a study of mackerel fillets associated with an outbreak of scombrotoxicosis, the doses of amines (cadaverine, histamine, putrescine, spermidine, spermine, tyramine) did not correlate to the development of symptoms characteristic of scombroid fish poisoning.[18]

DOSE RESPONSE

The dose response associated with scombroid fish poisoning is not completely defined because histamine concentration do not account for all of the clinical features of scombroid fish poisoning. Furthermore, the response to histamine depends on a number of variables including individual susceptibility, route of administration, body weight, and the presence of certain drugs (e.g., isoniazid).[19] Therefore, the threshold of toxicity varies substantially between different individuals. The oral administration of 100–180 mg histamine in grapefruit juice to 4 volunteers produced headache and flushing in one volunteer while the other volunteers remained asymptomatic.[20] The addition of this dose of histamine to 100 grams of high-quality tuna resulted in headache and flushing in 4 of 8 volunteers. In a volunteer study, the addition of 300 mg histamine (about 5 mg/kg body

weight) to 50 g fresh mackerel produced symptoms of mild scombroid poisoning (flushing, headache, oral paresthesias) in some, but not all volunteers.[21]

CLINICAL RESPONSE

The clinical presentation of scombroid poisoning resembles an acute allergic response that is mild and self-limited. Symptoms begin rapidly (i.e., 10 minutes–2 hours) after consumption of contaminated fish.[22] Adverse effects include headache, dysphagia, diffuse erythema, perioral paresthesias, pruritus, diaphoresis, conjunctival erythema, and gastrointestinal upset (nausea, vomiting, diarrhea, abdominal cramps). The most common symptoms in a review of 94 confirmed incidents of scombroid fish poisoning in Britain were erythematous rash, flushing, diarrhea, and headache.[23] However, the type and severity of gastrointestinal symptoms varies substantially between different outbreaks.[24] Typically, flushing appears on the face and upper body. Urticaria, angioneurotic edema, hypotension, palpitations, tachycardia, and bronchospasm occur occasionally.[25,26] Symptoms usually resolve within 8–12 hours, and symptoms rarely persist more than 24 hours.[27] Rare case reports associate scombroid fish poisoning with hypotension,[28] acute pulmonary edema, myocardial ischemia, subendocardial myocardial infarction, and cardiogenic shock in patients with pre-existing cardiovascular disease.[29,30] The differential diagnosis includes allergic responses and salmonellosis. Food allergies typically involve only a very small portion of individuals who consume the fish. The diagnosis of scombroid fish poisoning involves the rapid onset of typical symptoms of histamine poisoning after eating fish known to cause scombroid fish poisoning. The detection of high concentrations of histamine in samples from implicated fish is confirmatory. Attack rates during outbreaks of scombroid fish poisoning vary from about 50 to 100%, depending primarily on the histamine concentrations in the spoiled fish.[31,32]

DIAGNOSTIC TESTING

Conversion Units (Histamine)

$$1\,\text{ng/mL} = 0.111\,\text{nmol/L}$$

$$1\,\text{nmol/L} = 8.997\,\text{ng/mL}$$

Analytical Tests

Analytical methods for the detection of histamine include gas chromatography with flame ionization (requires sample cleanup to avoid matrix interference),[33] high performance liquid chromatography (HPLC),[34] ion exchange chromatography with integrated pulsed amperometric detection,[35] fluorometric methods,[36] and capillary electrophoresis.[37] More rapid testing methods for the detection of histamine involve enzyme-linked immunosorbent assay (ELISA) kits with sensitivities near 1–5 ppm.[16] There are three AOAC (Association of Analytical Chemists International, Gaithersburg, MD; http://www.eoma.aoac.org/) official methods of analysis for the quantitative determination of histamine in seafood. Official method 954.04 is a quantitative microbiological method, method 951.07 is a chromatographic method, and method 977.13 is a chromatographic method with fluorescence detection.[38] The latter method has been adopted by Codex Alimentarius as the internationally recognized method for the determination of this analyte in seafood. Food samples should be frozen if not analyzed promptly.[39] Histamine and *N*-methyl histamine concentrations in urine samples remain elevated at least 24 hours after the ingestion of fish contaminated with histamine concentrations up to about 20 mg/100 g tissue.[40]

Biomarkers

Although histamine concentrations in fish flesh is a good biomarker of spoilage secondary to inadequate storage, low histamine concentrations do not guarantee safety. Scombroid fish poisoning and histamine toxicity do not produce identical clinical syndromes; histamine concentrations in spoiled fish associated with scombroid fish poisoning usually exceed 50 mg/100 g tissue. Fresh fish typically contain negligible amounts of histamine (<0.1 mg/100 g).[41] Fish with histamine content below 5–10 mg/100 g tissue do not usually cause toxicity in most individuals, although symptoms of scombroid fish poisoning have been associated with histamine concentrations <5 mg/100 g tissue.[23] The ingestion of a 300 g meal of fish containing 10 mg/100 g wet weight by a 60-kg (132 lb) person results in a histamine dose of approximately 0.5 mg/kg body weight. Only 2 of 8 adults ingesting 90 mg (1.25–1.5 mg/kg) histamine developed symptoms of histamine toxicity.[14] The plasma histamine concentrations in blood samples from 5 symptomatic patients with scombroid fish poisoning ranged between 21.5 nmol/L and 47.8 nmol/L as measured by radioimmunoassay.[42] The samples were drawn 3–4 hours after ingestion of contaminated tuna, and all the histamine concentrations were below the upper limit of normal (10.8 nmol/L) by 24 hours after ingestion.

The US Food and Drug Administration (FDA) toxicity level for histamine in tuna is 50 mg/100 g (500 ppm) tissue, while the action level is 5 mg/100 g (50 ppm). European Union Directive 91/493 requires the

following conditions: 1) the average histamine concentration is below 10 mg/100 g (100 ppm), 2) no more than two of nine samples contain histamine concentrations between 100–200 ppm, and 3) no sample contains histamine concentrations above 200 ppm.[43] Most spoiled fish from outbreaks of scombroid fish poisoning contain histamine concentrations above 200 ppm and most of these implicated samples contain histamine concentrations exceeding 1000 ppm.[23] In spoiled fish, the distribution of histamine is not uniform with the highest concentrations usually near the gut and gills.[44] There is marked seasonal and fish-to-fish variation in the content of biogenic amines as well as susceptibility to decomposition.

Abnormalities

Scombroid fish poisoning typically is a mild, self-limited illness. There are no characteristic laboratory changes associated with this seafood-related illness, and serum chemistry and blood counts are usually normal.

TREATMENT

Treatment is supportive, and most cases of scombroid fish poisoning are mild and self-limited. Symptomatic patients often respond to antihistamines. Case reports suggest that the intravenous administration of H_1 receptor (25–50 mg diphenhydramine)[45] and H_2 receptor (300 mg cimetidine, 20 mg famotidine)[46] antagonists are efficacious in symptomatic patients. There are no clinical data to indicate that decontamination with activated charcoal improves the clinical outcome of this usually mild illness. Fluids, antiemetics, and bronchodilators should be administered as indicated by the clinical presentation. There are inadequate clinical data to support the use of corticosteroids.

AMATOXIN-CONTAINING MUSHROOMS

MUSHROOM IDENTIFICATION AND CLASSIFICATION

Fungi are neither plant nor animal. Because fungi lack chlorophyll and cannot manufacture their own food, these organisms must absorb nutrients from decaying organic matter (saprophyte) or from living organisms (parasite). Some species of fungi form symbiotic or mutually beneficial relationships with the roots of other plants in the form of a mycorrhiza. Mushrooms are the *fruiting bodies* of certain fungi. Most of the fungus consists of the *mycelium*, which is an extensive network of minute underground tubes (i.e., *hyphae*) that range in length from a few millimeters to hundreds of feet. Typically, the mycelium is hidden in a substrate (e.g., wood, soil, foods) where the hyphae secrete digestive enzymes and absorb nutrients through their cell walls. As the mycelium absorbs enough energy to reproduce, the mycelium generates new hyphae on the surface that develop into complex, spore-forming structures or fruiting bodies called *mushrooms*. The appearance of these fruiting bodies depends on heat, humidity, and the season. Variation in size, shape, color, and microscopic examination of spore morphology aids in the identification of mushroom species.

Poisonous mushrooms belong to the two higher fungus phyla: Basidiomycota (club fungi) and Ascomycota (sac fungi). The major difference between these two groups is the form of microscopic spores. The Basidiomycetes produce sexual spores (**basidiospores**) externally by budding on the ends of specialized cells called basidia. Basidiospores are forcibly discharged from basidia and then drop from the gills (or tubes for boletes from the order Boletales) located underneath the cap. Ascomycetes spores (**ascospores**) form by meiosis inside a tube-like structure called the ascus. The ascus expels the ascospores through a small lid or tip underneath the cap of the fungi. Although Ascomycetes contains over 50,000 diverse fungal species (e.g., *Penicillium* spp., *Gyromitra esculenta* (Pers.) Fr. or false morel), most poisonous mushrooms are the fruiting bodies of dikaryotic Basidiomycetes.

Identification

There is no single test that reliably distinguishes all poisonous mushrooms from nontoxic mushrooms ("no rule is the only rule"). Hence, identification of mushroom species requires careful observation of distinguishing characteristics species by species.[1] The use of rules (e.g., absence of tarnish on a silver spoon cooked in the same pot as the mushroom, presence of animal bite marks on the mushrooms) are unreliable methods to separate toxic from nontoxic mushrooms.[2] In fact, most poisonous mushroom species are morphologically similar to some edible species. Accurate identification of mushroom species requires careful observation of macroscopic characteristics including size, color, color changes, texture, odor, and anatomic characteristics of the mushroom. The size of mushroom spores is typically measured in microns. Microscopic analysis of the spores helps confirm the identification of the mushroom by evaluating the orientation of the hyphae in the gill tissue, the structure of the cap cuticle, and the shape and

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

size of the spore-forming structures (asci, basidia). Guides are available to help identify poisonous mushrooms based on macroscopic and microscopic characteristics.[3–6]

Mushroom Structure

Figure 37.1 demonstrates the general features of a mushroom using an *Amanita* species as an example. Natural trauma or deterioration during storage may alter these characteristics. In addition to the color, texture, and thickness of the flesh, the following macroscopic characteristics help identify poisonous mushrooms:[7,8]

Cap (Pileus): The cap supports the spore-producing surface (gills, basidia) of the mushroom. The covering of the cap is called the cuticle or the pellicle if the cuticle is easily removed. Important features include size, shape (cylindrical, conical, bell-shaped, umbonate, convex), color, color changes, surface characteristics (wet, dry, smooth, scaly, irregular, warts), and margin (straight, striate, incurved). See Figure 37.2.

Gills (Lamellae): This structure appears on the undersurface of the cap as thin, radiating blades along with the spore-forming structures. Distinguishing features include the alignment of the blades in relation to the stalk (plane, uplifted, depressed, funnel-shaped, umbilicate), the spacing, thickness, depth, and color.

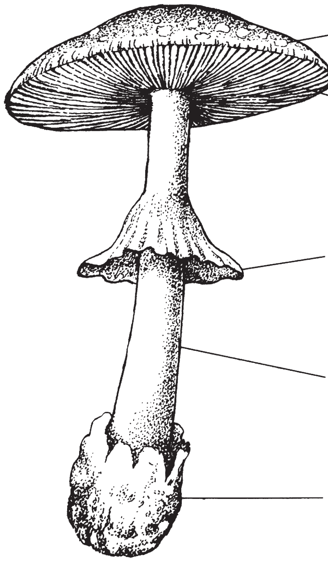

FIGURE 37.1. Morphologic structure of *Amanita phalloides*. Adapted from Ellenhorn MJ, Barceloux DG. Medical Toxicology: Diagnosis of Human Poisoning. 1st Edition, New York: Elsevier, 1988:1325.

Stalk (Stipe): This stem-like structure connects the cap to the ground and may contain a veil or annulus. The stalk pushes the spore-forming structures above the ground and allows the release of the spores into the air. The shape of the stalk varies from tapering downward to club-shaped and bulbous.

Ring (Annulus): Some mushrooms have a remnant of tissue, which remains on the stalk when the gills break through the veil. The shape may resemble a sheath, skirt, or collar. The position of the annulus may be oriented superior, inferior, medial, basal, or apical.

Veil: A specialized layer of tissue provides a protective cover for the developing mushroom. As the mushroom matures, a portion of the mushroom extrudes through this tissue to release the spores. The remnant of this tissue is the veil, which may or may not leave visible tissue on the stalk of the mature mushroom. There are two basic types of veils. A partial veil (inner veil) initially covers the gills, extending from the margin of the cap to the stalk. The remnant of the partial veil on the mature mushroom is the annulus. Occasionally, the partial veil adheres to the margin of the cap forming an appendiculate margin. The universal veil surrounds most of the immature mushroom. Remnants of the universal veil may form a volva at the base of the mature mushroom (e.g., most the *Amanita* species) or adhere to the underside of the partial veil. Pieces of the universal veil that adhere to the cap are called warts.

Cup (Volva): In some mushroom species (e.g., *Amanita phalloides*) visible remnants of the universal veil remain at the base of the stalk. These remains are called the volva. The shapes of these cups range from indistinct and scaly to sac-like and collar-like.

Specimen Collection

The mushroom specimen should be collected with as many features (cap, stem, cup) as intact as possible. The skirt and cup are important distinguishing features of *Amanita* species. The initial color of the flesh should be recorded along with any subsequent changes that result from trauma. Place the specimen in a paper bag and refrigerate. Plastic containers should be avoided. Samples of vomitus and lavage fluid should be filtered and refrigerated for later identification of spores.

Spore Identification

Spores are the microscopic "seeds" of the fungi. Spore identification involves determination of the color of the

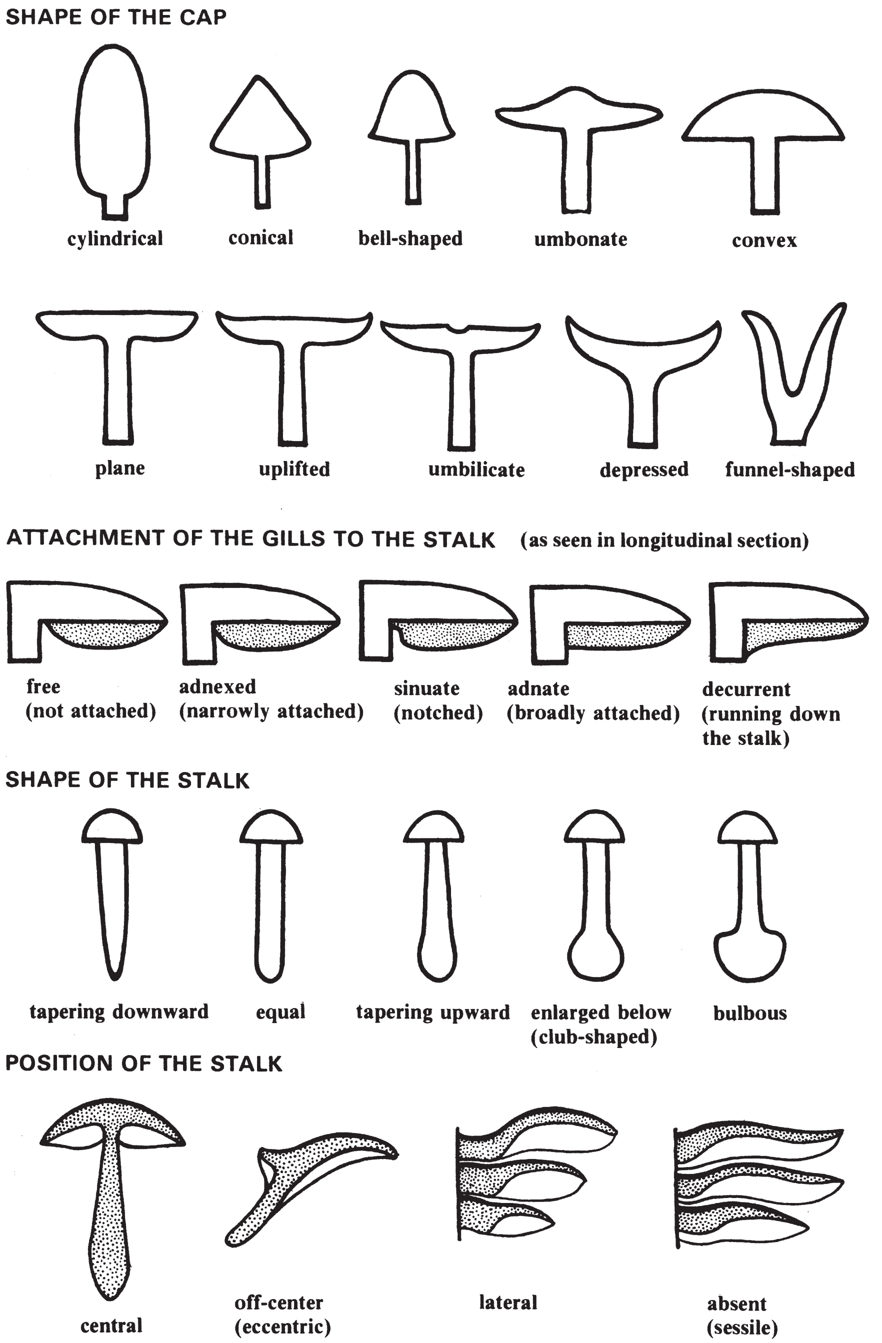

FIGURE 37.2. Nomenclature for the identification of mushrooms. From Arora D. Mushrooms demystified. A comprehensive guide to the fleshy fungi. 2nd ed. Berkeley, CA: Ten Speed Press; 1986:17.

spores through a spore print and microscopic examination of the shape and size of the spores. Because spores are not visible to the unaided eye, spores must be collected on a white paper for determination of color while using a standard color guide. The stalk of the mushroom is cut just below the cap, and the cap should be placed on the white paper with the gills facing the white paper. Covering the mushroom cap with a glass or bowl helps protect the spores from dispersing in air currents. After several hours, a characteristic color appears on the paper that is relatively resistant to environmental changes and constant within each mushroom species. The color of the mature gills does not always reflect the color of the spores. Spore prints may be difficult to obtain from young, soggy, or dried mushrooms. The application of various reagents helps to differentiate mushroom spores including the use of Melzer's reagent (20 g chloral hydrate, 0.5 g iodine, and 1.5 g of potassium iodide added to 20 mL of water) and less commonly Cotton Blue, aqueous potassium hydroxide, or sulphovanillin. Spores that turn grey, blue, or black after contact with Melzer's reagent are termed amyloid, whereas a more intense

red-brown is termed pseudo-amyloid as occurs with *Lepiota* species. No color changes occur following application of Melzer's reagent to nonamyloid spores. Examination of gastric contents or stool for spores requires filtering, extraction (diethyl ether), washing, separation (glycerol), and centrifuging. The top layer is examined under the microscope for color, presence of spores, shape, size, and wall thickness of the spores. Colorless or white spores in this layer are evaluated with Melzer's reagent to determine if color changes occur.

Clinical Classification

Poisoning by fungi also is known as mycetism or mycetismus. This type of poisoning results from the consumption of unspoiled fruiting bodies (i.e., mushrooms) that contain toxic substances. Exposures to mushrooms and their spores also produce other adverse effects including gastrointestinal (GI) intolerance (i.e., trehalase deficiency), infectious diseases, bacterial-related toxicity (e.g., botulism), and allergic reactions (asthma, rhinitis).[9] Respiratory allergies result from the inhalation of fungal spores by sensitized individuals. These patients are usually sensitive to a variety of common allergens including grasses, dust, dust mites, and animal dander. Although mushrooms may contain environmental contaminants (e.g., lead, arsenic, mercury, pesticides), the amount of the contaminants are usually too small to cause toxicity. Some fungal species (e.g., *Agaricus*) accumulate heavy metals, but there are no well-documented cases of acute heavy metal poisoning following the ingestion of these mushrooms. The production of toxic secondary metabolites by fungal species causes mycotoxicosis (e.g., aflatoxicosis, ergotism) following ingestion of food stuffs contaminated by these toxins.

Frequently, samples of the mushroom involved in a case of poisoning are not available. For clinical evaluation, mushroom poisoning has been classified into eight categories based on clinical features and the onset of symptoms.[5,10] These clinical syndromes include the following: 1) amatoxin poisoning, 2) orellanine nephrotoxicity, 3) gyromitrin (hydrazine-like) poisoning, 4) pantherina syndrome associated with *Amanita muscaria* and *A. pantherina*, 5) muscarine toxicity, 6) coprine (disulfiram-like) toxicity, 7) other mushroom syndromes from exposure to *Paxillus* and other mushroom species, and 8) gastroenteritis-producing mushrooms. In the absence of adequate mushroom specimens, a clinical classification provides a satisfactory mechanism to guide medical treatment. However, individual variations in susceptibility and the possible ingestion of multiple mushroom species limit the usefulness of this classification as the sole basis for treatment. The most important aspect of treatment remains the accurate identification of the fungal species involved, particularly by an experienced mycologist. Several aspects of the history aid the clinical identification of the type of mushroom poisoning including onset of symptoms, alcohol consumption, thirst, diaphoresis, headache, and fatigue.[11] Of these features, the onset of symptoms provides the best basis to separate mushroom poisoning into specific categories. Table 37.1 and Table 37.2 list the syndromes associated with rapid (<6 hours) and delayed (>6 hours) onset of symptoms, respectively. As with any classification, the onset of symptoms is not a strict criterion for diagnosing mushroom poisonings because of the possible ingestion of multiple toxic mushrooms, the variability of toxins in mushroom species, and differences in individual responses.

AMATOXIN POISONING

HISTORY

One of the first historical accounts of mushroom poisoning was by the Greek poet Euripides, who documented the fatal ingestion of mushrooms by a woman and three children. Later, historians posit that Euripides had actually detailed the fate of his own wife and children as they traveled to Icarus in 430 BC.[12] Other historical accounts suggest that mushroom poisoning may have been involved in the deaths of Charles VI of France, Pope Clement II, and the widow of Tzar Alexis. The first mushroom-related deaths documented in the American medical literature occurred during 1871 near Chico, California.[13] California consistently leads the United States in annual mushroom fatalities. The estimated average annual death rate from mushroom ingestions in Europe and North America combined ranges from 100 to 200, with most fatalities occurring in Central Europe.[14] The ingestion of *Amanita phalloides* (Vaill. ex Fr.) Link accounts for most of the deaths related to mushroom consumption, particularly in Europe. In the United States, adult fatalities are limited to the consumption of several amatoxin-containing species of the genera *Amanita* [e.g., *A. ocreata* Peck, *A. phalloides*, *A. verna* (Bull.) Lam., *A. virosa* (Fr.) Bertill.] and *Galerina*.

Between 1957 and 1964, 30 deaths were associated with mushroom ingestions in the United States. In the

Latency Period[a]	Syndrome	Principal Mushrooms	Symptoms
6–12 Hours	Gyromitrin Poisoning	*Gyromitra esculenta*	Delayed onset of gastrointestinal symptoms, headache, hypoglycemia followed by hepatorenal dysfunction, seizures, coma[b]
6–24 Hours (Average 10–12 hours)	Hepatorenal (amatoxin)	*Amanita* spp. (*A. bisporigera*, *A. ocreata*, *A. phalloides*, *A. verna*, *A. virosa*) *Galerina* spp. (*G. fasciculata*, *G. marginata*, *G. venenata*) *Lepiota* spp. (*L. brunneoincarnata*, *L. brunneolilacea*, *L. castanea*, *L. helveola*)	Delayed onset of intense diarrhea and other gastrointestinal symptoms during the 1st day, followed by a quiescent period and then progressive hepatorenal dysfunction
>24 Hours	Acromelalgia	*Clitocybe amoenolens*	Distal paresthesias/dysesthesias
1–3 Days	Rhabdomyolysis	*Tricholoma equestre*	Fatigue, muscle weakness, myalgias, and rhabdomyolysis
1–4 Days	*Amanita* Nephropathy	*Amanita* spp. (*A. proxima*, *A. smithiana*)	Gastroenteritis followed by relatively rapid onset of renal dysfunction compared with *Cortinarius* spp.
36 hours–14 Days	Orellanus	*Cortinarius* spp. (*C. orellanus*, *C. rubellus*)	Delayed onset of gastrointestinal symptoms, headache, thirst followed by progressive renal failure

[a]Time between ingestion and onset of symptoms.
[b]Distinguished from amatoxin syndrome by less intense diarrhea and later by lack of hepatotoxicity.

next 10 years, there were at least 57 hospitalizations and eight deaths resulting from mushroom toxicity in California alone.[15] During the early 1980s, the San Francisco Bay Area Poison Control Center experienced a 5-fold increase in calls regarding wild mushroom ingestions compared with the previous year.[16,17] Analysis of poison control center data indicates that most of wild mushroom exposures are clinically insignificant ingestions by children less than 6 years of age. In a 5-year analysis of California poison control data, approximately one-half of the 6,317 reported mushroom exposures did not experience any symptoms.[18] Of all the reported cases, 61 patients (1%) were admitted to critical care units and one patient died.

MYCOLOGICAL DESCRIPTION

Of approximately 5,000 mushroom species, less than 100 species are poisonous and about 35 species are known to contain amatoxins. Table 37.3 lists the known amatoxin-containing species that belong to the following fungal families: Amanitaceae (*Amanita* spp.), Agaricaceae (*Lepiota* spp.), and Cortinariaceae (*Galerina* spp.). Mushroom species in other genera may contain amatoxins, but there are no clinical data that associate ingestion of these mushroom species with human toxicity. Analysis of specimens from The North American mushroom, *Conocybe filaris* (Fr.) Kühner (*Pholiotina filaris*) demonstrated the presence of amatoxins,[19] but the European *Conocybe crispa* (Longyear) Singer and the common North American species, *C. lactea* (J.E. Lange) Métrod did not contain detectable concentrations of amatoxins.[20] Hepatoxicity following the consumption of *Conocybe* species is not well documented in the medical literature.[5]

Distinguishing toxic and nontoxic mushrooms is difficult as suggested by the numerous hospitalizations that occur after the consumption of wild mushrooms.[21] No single test distinguishes poisonous and nonpoisonous mushrooms (“no rule is the only rule”). Amatoxin-containing mushrooms possess no characteristic smell or taste, and these poisonous mushrooms often resemble edible mushroom species.

Amanita

Amanita species are large mushrooms that have an annulus (ring of death), volva (death cup), white gills unattached to the stalk, and colorless, broad ellipsoid spores that react to Melzer’s reagent (i.e., amyloid). The color of the cap varies from white to olive, olive-gray, yellow-green, or yellow-brown. Although the mature *Amanita phalloides* mushrooms usually have a distinctive olive green cap, white gills, and veil at the base of

TABLE 37.2. Rapid Onset (<6 hr) of Mushroom Poisoning

Latency Period[a]	Syndrome	Principal Mushrooms	Symptoms
0.5–2 Hours	Gastrointestinal	*Chlorophyllum molybdates*, *Agaricus* spp. (*A. hondensis*, *A. xanthodermus*), *Dermocybe sanguinea*, *Entoloma* spp. (*E. lividum*, *E. sinuatum*), *Macrolepiota venenata*, *Hebeloma crustuliniforme*, *Tricholoma pardinum*, and many other mushroom species	Nausea, vomiting, diarrhea, and abdominal pain
0.5–2 Hours	Muscarine	*Inocybe* spp. (*I. dulcamara*, *I. fastigiata*, *I. geophylla*, *I. patouillardii*, *I. umbrina*, and other species) *Clitocybe* spp. (*C. candicans*, *C. dealbata*, *C. ericetorum*, *C. phyllophila*, and other species) *Mycena pura*	Muscarinic symptoms including nausea, vomiting, watery diarrhea, abdominal cramps, miosis, blurred vision, diaphoresis, salivation, and muscle fasciculations
0.5–3 Hours	Psilocybin	*Psilocybe* spp. (*P. baeocystis*, *P. cubensis*, *P. pelliculosa*, *P. semilanceata*, and other species) *Panaeolus* spp. (*P. bohemica*, *P. cyanescens*, and other species) *Inocybe aeruginascens* *Gymnopilus junonius* *Panaeolina foenisecii*	Euphoria, disorientation, vertigo, headache, weakness, hallucinations, altered mood, drowsiness, and occasionally seizures and coma
15–30 Minutes[b]	Coprinus	*Clitocybe clavipes*, *Coprinus atramentarius*	Antabuse-like reaction with nausea, vomiting, headache, flushing, vertigo, diaphoresis, tachycardia, and metallic taste
0.5–3 Hours	Pantherina	*Amanita* spp. (*A. aprica*, *A. gemmata*, *A. muscaria*, *A. pantherina*, *A. regalis*)	Euphoria, ataxia, agitation, disorientation, euphoria, anxiety tremor, ataxia followed by prolonged sleep
1–2 Hours	Paxillus	*Paxillus involutus*	Nausea, vomiting, diarrhea, weakness, abdominal pain along with hemolytic anemia, jaundice, and renal dysfunction[c]

[b]Minutes after ethanol consumption. Mushroom ingestion can occur up to 72 hours prior to ethanol ingestion.
[c]Minor reactions may occur during months to years prior to the development of the Paxillus syndrome.

the stem, several factors alter the appearance of this mushroom including weather and soil conditions, trauma, season, location, and age of the specimen.[16] The cup may not be present because of the loss of the lower portion of the stalk during collection of the specimen.

Common Name: Death Cap, Deadly Angel, Deadly Amanita, Destroying Angel, Deadly Agaric

Family: Amanitaceae

Scientific Name: *Amanita phalloides* (Vaill. ex Fr.) Link

Physical Description: The grayish olive to greenish yellow cap is 5–15 cm (~2–10 in.) with light greenish olive margin and a shiny, dry surface containing dense, dark grayish olive fibrils at the center. The gills are free with intercalated gills, which contain white spore masses that turn blue-black following application of Melzer's reagent. The stalk contains a membranous volva surrounding an enlarged bulb at the base. The stalk gradually tapers above the bulb where the remains of a partial veil (annulus) appear 1–1.5 cm (~0.5 in.) below the cap.

[a]Mushroom species most commonly associated with amatoxin poisoning.
[b]Synonyms: *G. autumnalis*, G. unicolor.

The white stalk usually contains a scattering of grey-olive scales. Spores are globose to ellipsoidal, ranging in size from 7–12.8 × 5.5–10.2 µm in diameter.

Distribution and Ecology: In the United States, *Amanita phalloides* occurs primarily in the cool coastal forests of the west coast (Northern California, Pacific Northwest) as documented by reports of fatal ingestions.[22] However, *A. phalloides* also inhabits the mid-Atlantic coast and oak woodlands of the northeastern United States. These mushrooms flourish during the fall, particularly after warm, heavy rains. *A. phalloides* is the predominant European poisonous mushroom, particularly in Central and Occidental Europe. This species occurs primarily in deciduous and mixed deciduous forest, especially near oak trees during August to October. *Amanita phalloides* is also widespread in southeastern Australia including the Melbourne suburbs, New South Wales, Tasmania, and Victoria.[23]

Common Name: Destroying Angel, Spring Amanita, White Death Cap, Fool's Mushroom

Family: Amanitaceae

Scientific Name: *Amanita verna* (Bull.) Lam.

Physical Description: This species is similar to *A. phalloides* with the exception of the overall white appearance. The cap is hemispherical in young specimens, and the 4–8 cm (2–3 in.) mature cap becomes more convex to flat than *A. phalloides*. The gills of *A. verna* are free and they do not contact the stem. The white stalk contains a ring in the upper portion and a cup at the base. Like spores from *A. phalloides*, the *A. verna* spores are colorless, broadly elliptical, and stain blue-black with Melzer's reagent.

Distribution and Ecology: *Amanita verna* occurs in the warmer regions of Europe from spring until autumn, whereas *Amanita virosa* inhabits the mountainous regions with conifer forests.

Common Name: Destroying Angel, White Amanita, Angel of Death, White Death Cap

Family: Amanitaceae

Scientific Name: *Amanita virosa* (Fr.) Bertill.

Physical Description: The appearance of this large, white mushroom is similar to *A. verna*. Like all *Amanita* species, the stalk contains a ring below the cap and a volva at the base. The gills are free with a white spore print. The 6–11 cm (2–4 in.) cap is smooth with a silky sheen in dry weather. The

shape of the cap varies from cone- to egg-shaped in young specimens to cone-shaped in older specimens. The cap of mature specimens frequently has a central, navel-like depression.

Distribution and Ecology: The distribution of *A. virosa* is more localized in Europe (e.g., evergreen forests of Scotland and Upper Bavaria) compared with *A. phalloides*.[5]

Galerina

There are at least seven known species of *Galerina* that contain amatoxins including *G. badipes* (Fr.) Kühner, *G. beinrothii* Bresinsky, *G. fasciculata* Hongo, *G. helvoliceps* (Berk. & M.A. Curtis) Singer, *G. marginata* (Batsch) Kühner, *G. sulciceps* (Berk.) Singer, and *G. venenata* A.H. Sm.[5,24] These small brown mushrooms have a somewhat de-curved cap with brownish spore prints.

Common Name: Marginate Pholiota

Family: Cortinariaceae

Scientific Name: *Galerina marginata* (Batsch) Kühner (*Galerina autumnalis*, *Galerina unicolor*)

Physical Description: This small mushroom has a 1.4–5 cm (~0.5–2.0 in.) cap that contains ochre-colored gills. The spore print is dust-brown. The shape of the cap from immature specimens is almost hemispherical with a de-curved margin, but more mature specimens have a convex shape. The ochre-colored stalk contains a ring, but no volva. Below the ring, the flesh of the stalk is relatively smooth without scales.

Distribution and Ecology: This white-rot fungus is widely distributed, primarily on rotting wood or debris of conifers (hardwoods) in European and American forests.

Lepiota

Lepiota species produce small to medium-sized mushrooms with bare to conical, wart-containing caps typically <10 cm (4 in.) in size. The spores are pseudo-amyloid. Despite their relatively small size, case reports associate severe hepatorenal dysfunction with ingestion of these mushroom species including *Lepiota brunneoincarnata* Chodat & C. Martín, *Lepiota helveola* Bres., and *Lepiota subincarnata* J.E. Lange (*L. josserandii*).[25–27]

Common Name: Star dapperling

Family: Agaricaceae

Scientific Name: *Lepiota helveola* Bres.

Physical Description: This small to moderately large mushroom has a 1.5–6 cm (~0.5–2.5 in.) cap that is hemispherical to convex in young specimens and more umbonate with a slightly depressed center in older specimens. The pink to flesh-colored cap contains white to reddish tinged gills and elliptical spores that are pseudo-amyloid with Melzer's reagent. The free gills contain a white mass of spores. The stalk contains a ring, but no definite cup at the base.

Distribution and Ecology: This relatively rare fungus occurs in decaying matter at the edge of forests and nearby grassland in Europe.

EXPOSURE

The actual incidence of mushroom toxicity in the United States is difficult to estimate because poisoning often occurs in clusters, and the reporting of adverse reactions to mushroom ingestion is not required by US law. Amatoxin poisoning usually results from the misidentification of *A. phalloides* as an edible mushroom species, such as *Amanita fulva* (Schaeff.) Fr., *Agaricus* spp., *Macrolepiota procera* (Scop.) Singer (*Lepiota procera*), and *Tricholoma portentosum* (Fr.) Quél. Several other *Amanita* species (e.g., *A. virosa*, *A. verna*, *A. ocreata*, *A. bisporigera*) are more prevalent than *A. phalloides* in the United States. However, case reports of fatalities following consumption of other amatoxin-containing *Amanita* species (e.g., *A. verna*,[28] *A. virosa*[29]) are much less common than *A. phalloides*. Rare case reports associate fatalities with the ingestion of amatoxin-containing *Galerina* species (*G. marginata*, *G. venenata*).[30,31] In addition, several American *Lepiota* species (*L. helveola* Bres., *L. castanea* Quél., *L. felina* (Pers.) P. Karst.) contain amatoxin, but to date no cases of toxicity have been reported following ingestion of these mushrooms in the United States. Because of the wide variations in location and toxicity of *Amanita*, *Galerina*, and *Lepiota* species, the regional poison control center is an important source of information regarding poisonous mushrooms in the local area.

PRINCIPAL TOXINS

Physiochemical Properties

The three major types of toxic peptides in *Amanita* species are amatoxins, phallotoxins, and virotoxins.[32,33] These toxins contain a sulfur-linked tryptophan unit and unusual hydroxylated amino acids. Amatoxins, such as α-amanitin (CAS RN: 23109-05-9) or β-amanitin (CAS RN: 21150-22-1), are the bicyclic octapeptides responsible for the fatalities associated with the ingestion of amatoxin-containing mushrooms belonging to the genera *Amanita*, *Galerina*, and *Lepiota*.[34] Figure 37.3

	R_1	R_2	R_3	R_4	R_5	LD_{50} (mg/kg)
α-Amanitin	CH_2OH	OH	NH_2	OH	OH	0.3
β-Amanitin	CH_2OH	OH	OH	OH	OH	0.5
γ-Amanitin	CH_3	OH	NH_2	OH	OH	0.2
ε-Amanitin	CH_3	OH	OH	OH	OH	0.3
Amanin	CH_2OH	OH	OH	H	OH	0.5
Amaninamide	CH_2OH	OH	NH_2	H	OH	0.3

Amanullinic Acid	CH_3	H	OH	OH	OH	>20
Proamanullin	CH_3	H	NH_2	OH	H	>20

FIGURE 37.3. Chemical structure of amatoxins.

demonstrates the structure of eight amatoxins, which are composed of an amino acid ring bridged by a sulfur atom. The major amatoxins that cause hepatorenal toxicity are α-amanitin, β-amanitin, and γ-amanitin. These compounds are present in some *Galerina* and *Lepiota* species as well as *Amanita* species. The amatoxin-containing species of *Amanita* also contain several cyclic heptapeptides called phallotoxins (phalloidin, phallisin, phalloin, phallacidin, phallisacin).[35,36] Although phalloidin is a potent parenteral animal hepatotoxin, the poor GI absorption of phallotoxins probably limits any systemic toxicity following ingestion. Phallotoxins are bicyclic peptides containing cysteine, whereas virotoxins are monocyclic peptides containing serine. Virotoxins include ala–viroidin, viroisin, deoxoviroisin, viroidin, and deoxoviroidin. In experimental animals after intraperitoneal injection of virotoxins and phallotoxin, the histological changes of hepatocytic vacuolization and intracytoplasmic erythrocyte accumulation are similar;[37] however, the role of virotoxins in human toxicity is unclear. Amatoxins are stable compounds that do not degrade during cooking or drying at 250 °C–280 °C (480 °F–535 °F). These compounds resist freezing at –25 °C (13 °F), and ingestion of *Amanita phalloides* mushrooms stored in a freezer for 7–8 months produced fatal hepatoxicity.[38] However, amatoxins decompose slowly when stored in open, aqueous solutions or following prolonged exposure to sun or neon light.

TABLE 37.4. Approximate Content of Principal Amatoxins and Phallotoxins in *Amanita Phalloides*

Toxin	Weight (mg/g)*
α-Amanitin	1.0–2.5
β-Amanitin	1.2–3.25
γ-Amanitin	0.2–0.65
Phalloidin	0.9–2.2
Phallacidin	2.4–4.3
Phallisacin	1.7–6.0

*Dry weight.

Poisonous Parts

There are approximately 35 amatoxin-containing mushroom species in three genera: *Amanita*, *Galerina*, and *Lepiota*. Amatoxins probably occur in most *Amanita* mushroom species, even in minute amounts in edible mushroom species. *Amanita phalloides* is the most toxic amatoxin-containing mushroom species with an amatoxin content of about 2–3 mg/g dry tissue. Table 37.4 demonstrates the approximate amatoxin and phallotoxin content of a several collections of samples from *A. phalloides* mushrooms. Consequently, 1–3 fresh mushrooms (i.e., about 50 g) probably contain lethal quantities of amatoxin depending on the amatoxin concentrations.

A variety of factors affects the amatoxin concentrations in *Amanita* species including plant part, environmental factors, location, type of toxin, and soil type as well as significant variation between *Amanita* species. A study of three *Amanita phalloides* specimens demonstrated the highest amatoxin content in the ring, gills, and cap, whereas the bulb and volva contained smaller amatoxin concentrations and larger concentrations of phallotoxins.[39] Similarly, examination of 25 fruiting bodies from *Amanita phalloides* specimens collected in France demonstrated relatively high concentrations of α-, β-, and γ-amatoxins in the cap, gills, ring, and stalk compared with the bulb and the volva (cup) as measured by high performance liquid chromatography (HPLC).[40] In contrast, the concentration of phallotoxins (phallacidin, phallisacin, phalloidin, phallisin, phalloin) was higher in the bulb and cup compared with the cap, gills, ring, and stalk. Specimens of amatoxin-containing species with the more toxic specimens typically contain about 0.1–0.4% amatoxins.[41] Generally, amatoxin-containing *Amanita* species other than *A. phalloides* contain less amatoxin (e.g., *A. virosa*: 1.2–2.6 mg/g dry tissue) compared with the amatoxin content of *A. phalloides*. Additionally, the ratio of α-amatoxin to β-amatoxin varies between the amatoxin-containing species of *Amanita* and individual specimens. For example, *A. virosa* contains primarily α-amatoxin, whereas *A. phalloides* contains relatively high concentrations of β-amatoxin.[42] Some American samples of *A. virosa* contain relatively small amounts of amatoxin, but relatively large concentrations of virotoxins, whereas some European specimens contain amatoxin concentrations similar to local specimens of *A. phalloides*.[5] *A. bisporigera* G.F. Atk. is one of the most hepatotoxic toxic American *Amanita* species, particularly in the Midwestern and Eastern United States.[43] *A. verna* contains variable amounts of amatoxins. Examination of a few American and European specimens of *Galerina marginata* (*G. autumnalis*) yielded small amounts of β-amanitin and 0.1–0.8 mg α-amanitin/g dry weight.[44] *Lepiota* species (e.g., *L. brunneoincarnata* Chodat & C. Martín, *L. subincarnata* J.E. Lange, *L. boudieri* Guég) can contain substantial amounts (1.75–3.5 mg/g dry weight) of amatoxins.[45] Typically, these species contain α-amanitin and lesser amounts of γ-amanitin, but β-amanitin and phallotoxins are usually not detectable.

Toxic *Galerina* species (e.g., *G. marginata*) contain 0.8–1.5 mg of α- and β-amanitin per gram dry weight. In a study of 27 specimens of *G. marginata* from Alsace-Lorraine and Franche-Comté, the mean concentrations (μg/g fresh weight) of total amatoxins in three groups of these specimens were as follows: 78.17 ± 10.08 ($n = 6$); 96.88 ± 12.82 ($n = 11$); and 243.61 ± 16.54 ($n = 10$).[46] The hepatorenal syndrome following the ingestion of amatoxin-containing *Galerina* mushrooms is similar to the toxic *Amanita* species despite the absence of phallotoxins in the former mushrooms. Consequently, amatoxins are the primary toxic constituents of these hepatotoxic mushrooms rather than phallotoxins or virotoxins.

Mechanism of Toxicity

Amatoxins are potent inhibitors of mammalian DNA-dependent RNA polymerase II at very low concentrations (5–10 ng/mL); therefore, amatoxins interfere with protein synthesis via inhibition of elongation essential to transcription.[47] Those cells (e.g., liver, kidney, and intestinal cells) with the highest replication rates and most direct contact with the amatoxins develop necrosis. There is substantial variation in the toxicity of amatoxins between animal species. Higher mammals including humans, dogs, cats, and guinea pigs are relatively sensitive to amatoxins, whereas lower mammals (e.g., rodents) are relatively resistant to the effects of amatoxins because nonmammalian polymerases show little sensitivity to amanitins.[41] Although parenteral administration of phallotoxins to animals stimulates the polymerization of G-actin and stabilizes the F-actin filaments, the role of phallotoxins in producing hepatorenal failure in humans is limited by the lack of GI absorption of these compounds.

Liver

Amatoxin poisoning produces massive centrilobular hepatic necrosis characterized by centrilobular hemorrhage with preservation of hepatocytes limited to the larger triads. *In vitro* studies suggest that the Na^+-taurocholate cotransporter polypeptide facilitates uptake of α-amanitin by liver cells;[48] recent studies indicate that the organic anion-transporting polypeptide 1B3 (OATP1B3) is the human hepatic uptake transporter for amatoxins.[49] Once inside the cell, α-amanitin binds DNA-dependent RNA polymerase II at each translocation step in the hepatocytes,[50] resulting in the inhibition of protein synthesis and cell necrosis.[51]

Postmortem examinations of patients dying from amanitoxin-induced hepatic failure demonstrate widespread vacuolar degeneration of the liver cells. Macroscopic changes include diffuse jaundice, cerebral edema, subserosal petechiae, pulmonary congestion, yellow atrophy of the liver with diffuse subcapsular hemorrhaging, and evidence of hemorrhage throughout the body.[52] Some periportal regenerative changes and lobular collapse may appear depending on the survival time since ingestion. The most striking anatomic changes occur in the nuclei, where chromatin clumps appear

along the periphery leaving the central portion clear.[53] Typically, these changes are not permanent if the patient survives, and surviving patients do not usually develop cirrhosis.

Kidney

Characteristic renal lesions following ingestion of amatoxin-containing mushrooms involve acute tubular necrosis with deposition of massive quantities of hyaline casts in the tubules. Histological examination does not usually demonstrate glomerular lesions. Macroscopically, the kidney typically appears dark red with extravasation of blood, especially in the cortical region.[52] Dehydration and hypovolemia may contribute to the development of acute tubular necrosis.[54] A case report of a renal biopsy examined by electron microscopy suggests that diffuse interstitial renal fibrosis may develop 1–2 months after *Amanita phalloides* ingestion without evidence of inflammatory changes.[55] Both proximal and distal convoluted tubules contain large vesicles within their endoplasmic reticulum and exhibit a loss of brush borders. Basement membranes are thickened without disruption. Another case report associated the development of Fanconi-type renal tubular acidosis with *Amanita phalloides* ingestion.[56]

Central Nervous System

Central nervous system effects probably result from hepatorenal failure rather than direct toxic effects of amatoxins. Case reports of fatal amatoxin poisoning document cerebral edema and cerebellar tonsillar herniation with fatty infiltration and mild hemorrhage of the subendocardial region.[16] Both neuropathological and myocardial changes following fatal amatoxin poisoning are variable and nonspecific because of terminal events, such as hyperpyrexia, sepsis, and cardiovascular collapse.

DOSE RESPONSE

There is significant inter- and intraspecies variation in the concentration of amatoxins in mushrooms depending on a number of factors including growing conditions, time of year, and humidity. Therefore, accurate prediction of toxicity based on the quantity of mushrooms consumed is difficult. Although all animal species develop adverse effects following exposure to amatoxin, there is substantial variation in the response of various species to similar doses. The estimated lethal dose of amatoxin for humans is approximately 0.1–0.3 mg/kg.[57] This dose correlates to 50–300 g of amatoxin-containing mushrooms.

TOXICOKINETICS

Kinetics

The GI absorption of amatoxins is rapid based on animal data and the appearance of amatoxin in the urine of a suicidal patient within 1.5–2 hours after ingestion.[58] In animal studies, the volume of distribution of α- and γ-amanitin is similar to the volume of the extracellular space.[59] The plasma elimination half-lives of these amatoxins ranged from approximately 30–45 minutes. Amatoxins are not bound to plasma proteins.[60] Case series of patients with amatoxin poisoning support the rapid elimination of amatoxins from the blood.[61] These human studies indicate that most amatoxins are cleared from the plasma within 12–24 hours after ingestion.[62,63] In a study of amatoxin poisoning, analysis of plasma samples drawn from patients between 9–18 hours after amatoxin ingestion did not detect α- or β-amanitin in five of nine samples.[62] One sample contained 20 μg α-amanitin/L and three other samples contained β-amanitin concentrations ranging from 23.5–162 μg/L. Elimination of absorbed amatoxins occurs primarily by renal excretion with smaller amounts excreted in the bile.[64] Renal elimination of amatoxins continues for 2–3 days after ingestion as a result of the uptake of amatoxins by the kidney. Although the duodenal aspirate of some patients with amatoxin poisoning may contain high concentrations of α- or β-amanitin, the amount eliminated by the bile is limited by the relatively small amount of biliary fluid. In a study of the gastroduodenal fluid from 12 patients with amatoxin poisoning, the aspirate did not contain detectable amounts of α- or β-amanitin in 8 of the 12 patients, when the samples were obtained 18–48 hours after ingestion.[62] Only gastroduodenal fluid samples from 2 patients contained high concentrations of α- or β-amanitin, when obtained 30 hours and 84 hours after ingestion. Amatoxins in the feces probably result from amatoxins that are not absorbed by the GI tract.[62] Amatoxins probably do not cross the blood–brain barrier.

Pregnancy

Samples of blood and amniotic fluid withdrawn from a woman in the eighth month of pregnancy demonstrated that the α-amanitin concentration was detectable in maternal blood, but not in the amniotic fluid.[65] The child was born without complications or anomalies. A case report documented the delivery of a healthy infant despite the development of moderate amatoxin poisoning during the 1st trimester[66] and 2nd trimester[67] of pregnancy. Follow-up of the children indicated normal development. A small case-control study did not detect an increased prevalence of major or minor anomalies in

women poisoned by amatoxin-containing mushrooms during pregnancy.[68] However, the statistical power of the study was limited by the inclusion of only 5 women poisoned during the 1st trimester of pregnancy.

CLINICAL RESPONSE

Onset of Symptoms

The clinical presentation of hepatorenal toxicity is similar between various amatoxin-containing species within the genera *Amanita*, *Galerina*, and *Lepiota*.[69] The onset of GI symptoms after the ingestion of amatoxin-containing mushrooms usually ranges from 6–24 hours with an average of approximately 10–12 hours. The delayed onset of GI symptoms is an important diagnostic tool, but the presence of a short onset of GI symptoms does not exclude the ingestion of amatoxin-containing mushrooms if other mushrooms or substances with GI effects were also ingested. The GI effects of most nonlethal mushrooms develop with 2 hours after ingestion. Characteristically, amatoxin poisoning has the following three stages after the onset of GI symptoms: 1) gastrointestinal phase, 2) latent period representing the time required for the amatoxins to noncompetitively bind to intranuclear RNA polymerase II and disrupt protein synthesis, and 3) the hepatorenal phase.

Gastroenteritis Phase

The initial features of toxicity involve a profuse, watery diarrhea manifest by the abrupt onset of severe abdominal pain, nausea, vomiting, and bloody diarrhea. This phase usually lasts about 12–36 hours. Fever, tachycardia, hyperglycemia, hypoglycemia, dehydration, and electrolyte imbalance may occur during this phase.

Latent Period

With adequate fluid and electrolyte replacement, a remission of symptoms occurs during a subclinical elevation of serum hepatic aminotransferase enzymes. If mushroom-related toxicity is not suspected during this second latent phase, the patient may be discharged with the diagnosis of gastroenteritis.

Hepatorenal Phase

Within 3 to 4 days after ingestion, hepatic dysfunction and fulminant hepatic failure becomes clinically obvious with jaundice, coagulopathy, hemorrhage, hypoglycemia, delirium, confusion, and coma.[70] Biochemical signs of liver damage may develop within 36–48 hours after ingestion of the amatoxins.[71] Coagulopathies, metabolic acidosis, conduction abnormalities, hemorrhage, and sepsis frequently complicate severe cases. Progression from stage I to stage III/IV hepatic encephalopathy may be rapid.[27] Renal failure accompanies liver failure in most fatal cases, but occasionally renal dysfunction rather than hepatic failure is the most prominent clinical feature of amanita toxicity.

Outcome

Current mortality rates vary between <10% and 30% because of the wide variation in the amount of toxin ingested, individual susceptibility, and the overall health of the patient. Recently, mortality rates have declined with improvements in supportive care for liver failure, particularly in the absence of cerebral edema.[72] In a series of 24 patients treated with supportive care and serial activated charcoal for the first 48–72 hours, the mortality rate was 9%.[56] Death usually results from hepatic encephalopathy, cerebral edema, and multiorgan failure 4–9 days after ingestion. Risk factors for fatal outcomes following ingestion of amatoxin-containing mushrooms include age <10 years, short latency between ingestion and onset of GI symptoms, and severe coagulopathy. In surviving patients, a slow resolution of the hepatic necrosis begins on day 4–day 5 with decreasing serum hepatic aminotransferases and improving prothrombin activity. Most surviving patients recover without sequelae.[73] However, follow-up studies of amatoxin poisoning suggest that some patients may develop chronic active hepatitis with immune complexes, antismooth muscle antibodies, and a persistent elevation of serum hepatic aminotransferases.[74] A case series of 64 Italian patients with amatoxin poisoning documented the persistence of chronic active hepatitis and a lobular hepatitis at least 6 months after moderate to severe *Amanita* mushroom poisoning.[75] Case reports associate *Lepiota* mushroom poisoning (*L. helveola*, *L. brunneoincarnata*) with the development of a mixed polyneuropathy beginning at least 8 days after mushroom ingestion.[76] Manifestations of the polyneuropathy include weakness in the lower extremities, loss of deep tendon reflexes, and alteration of sensation. Weakness in the lower extremities in several patients persisted at least one year.

Pregnancy

There are few data on the effect of amatoxins on the fetus. Case reports suggest that fetal damage may result

from the ingestion of amatoxins by the mother, but the evidence for this damage is contradictory.[71] A 22-year old woman developed moderately severe amatoxin poisoning during her 11th week of pregnancy.[66] She was treated with silymarin and *N*-acetylcysteine, and she delivered a full-term, healthy infant without complications. Follow-up examination of the infant at 2 years detected no evidence of hepatic or neurological injury. Other case reports support the lack of liver injury in infants born to a mother poisoned by *A. phalloides* ingestion.[77]

DIAGNOSTIC TESTING

Analytical Methods

α-Amanitin can be identified by thin-layer chromatography, radioimmunoassay (RIA),[78] enzyme-linked immunosorbent assay (ELISA),[79] HPLC,[35,36] capillary zone electrophoresis with photodiode array detection,[80] gas chromatography (GC), gas chromatography/mass spectrometry (GC/MS), or multistage linear ion trap mass spectrometry.[81] The calculated limit of detection for the latter method in serum or liver samples is 0.50 ng/g. A rapid fluorescent method is available for the detection of α- and β-amanitin using ethidium bromide fluorophores at 560 nm and 525 nm, respectively.[82] Vomitus, blood, and urine should be collected from the patient and stored under refrigeration until analyzed. The Wieland-Meixner test (Table 37.5) is a crude field test for the presence of amatoxins that is relatively sensitive, but negative results do not guarantee the absence of other mushroom toxins.[83] The basis of this test is the color changes associated with the acid-catalyzed reaction of α-, β-, and γ-amanitin with lignin present in pulp paper. The detection limit is about 0.2 mg/mL, which is substantially below the concentration in most toxic species. Consequently, the Wieland-Meixner test is sensitive to the presence of amatoxins in mushrooms, but exposure to excessive heat and sunlight produces false-positive results. Additionally, *in vitro* studies suggest that the presence of psilocin (*Psilocybe* spp., *Panaeolus* spp., *Conocybe* spp.) and, to a lesser extent, 5-substituted tryptamines (*Panaeolus* spp.), cause false-positive reactions with the Wieland-Meixner test.[84] The presence of 5-substituted tryptamines (bufotenine) produces a reddish-brown color on the Wieland-Meixner test, whereas the presence of 4-substituted tryptamines (e.g., psilocin) produces a gray to pale blue color that can be confused with the blue color associated with amatoxins. Analysis of α-amanitin by HPLC has detection limits of approximately 10 ng/mL.[85,86] Radioimmunoassay techniques can detect α-amanitin concentrations in biological samples near 0.1 ng/mL in plasma, but some cross-reactive may occur with other compounds.[87]

TABLE 37.5. Wieland-Meixner Test

Squeeze the fresh mushroom, preferable in a garlic press, and place a drop of the juice onto a lignin-containing paper (e.g., print-free newspaper, cheap pulp paper).* If inadequate amounts of fresh tissue are present, thoroughly pulverize the remaining portion of the mushroom on the paper. A methanol-extract of a dry mushroom may be applied to the paper if a fresh mushroom is not available.
Circle the area of wetness with a marker, and also circle a blank control area on the paper outside the area where the tissue was pulverized.
Dry the wet spot with gentle, warm air (e.g., hair dryer).
Add a drop or two of concentrated (10–12 N) hydrochloric acid to the sample circle and to the control circle.
Observe the circles for the appearance of blue discoloration, usually within 1–2 minutes after application of the acid. The presence of trace amounts of α-amanitin requires longer (10–20 minutes) for the color change.

*Perform indoors away from sunlight and excessive heat. Low amatoxin concentrations can cause a delayed reaction and therefore a second reading 30 minutes after the first reading should be done to detect low amatoxin concentrations.

Biomarkers

α- and β-Amanitin concentrations in blood and urine samples confirm exposure to amatoxin-containing mushrooms, but there are few data to correlate blood amanitin concentrations to symptoms or outcome. Urine α-amanitin concentrations are usually higher than plasma α-amanitin concentrations, and urine samples are the preferred biological sample for confirmation of exposure to amatoxins because these compounds disappear rapidly from the blood.[88] These compounds are usually detectable in plasma and urine up to about 36 hours and 4 days, respectively, after ingestion.[62] Case reports indicate that α- and β-amanitin appear in the urine within $1^1/_2$–2 hours after ingestion of amatoxin-containing mushrooms as measured by radioimmunoassay with limits of detection near 2.5 ng/mL.[58] However, even urine α-amanitin concentrations may be low (i.e., ≤6 ng/mL) 12 hours after ingestion despite a fatal ingestion of amatoxin-containing mushrooms.[34]

Abnormalities

Initial laboratory values may reflect the dehydration and electrolyte imbalance associated with the gastrointestinal phase of amatoxin poisoning. Amatoxin poisoning produces the onset of hepatorenal dysfunction 1–2 days after ingestion, manifest by increases in serum

bilirubin, serum hepatic aminotransferases, serum creatinine, and a coagulopathy (increase prothrombin time, reduce fibrinogen and coagulation factors II, V,VII, and X). Serum hepatic aminotransferase values peak between 2–4 days after ingestion, whereas serum bilirubin concentrations peak in the blood from survivors 4–5 days after ingestion.[72] The coagulopathy and hyperbilirubinemia may continue to deteriorate in patients with severe amatoxin poisoning.[89] Hypoglycemia may complicate the onset of hepatic encephalopathy. Case reports indicate that clinical or biochemical evidence of pancreatitis occurs during the later stages of amatoxin poisoning.[90] In general, the serum hepatic aminotransferases are lower in survivors than in nonsurvivors, but the extent of the rise in serum hepatic aminotransferase values does not accurately predict survival.[16] Transient proteinuria may occur in the absence of renal insufficiency.[91] Serum ammonia concentrations reflect the severity of liver dysfunction, but this test alone does not necessarily predict the severity of amatoxin poisoning.

TREATMENT

Stabilization

Treatment of amatoxin poisoning is primarily supportive with initial attention directed toward the aggressive correction of the acid-base, fluid, and electrolyte imbalances caused by the gastrointestinal phase of the poisoning. Any patient with altered mental status should be immediately evaluated for hypoglycemia. Patients presenting late in the course of amatoxin poisoning should be evaluated for hepatorenal failure, hemorrhage, and coagulopathy. Fresh-frozen plasma, vitamin K (10 mg daily for 3 days), and packed red blood cell transfusions may be necessary to correct the coagulopathy and associated bleeding. A careful history is necessary to evaluate the severity of the ingestion including time and location of mushroom ingestion, onset of symptoms in relation to ingestion, the number of mushroom species ingested, and the location of any remaining specimens. Any persons ingesting the same mushrooms should be evaluated immediately. Submitted mushroom remnants should be evaluated by an expert mycologist for identification.

Decontamination

Most patients with amatoxin poisoning develop severe gastrointestinal symptoms prior to presentation to a health care facility; therefore, decontamination measures are not necessary. Vomitus should be stored for evaluation for the presence of amatoxins or spores. Patients should receive a dose of activated charcoal. Because of the enterohepatic circulation of amatoxins, serial activated charcoal (20–40 g every 3–4 hours) has theoretical value, but the efficacy of this therapy has not been tested in clinical settings. The toxicokinetics of amatoxins suggest that activated charcoal may be discontinued by 48 hours after ingestion. Gastroduodenal aspiration is a potential therapeutic modality to enhance the elimination of amatoxins, but there are limited data on the efficacy of this treatment, particularly when the amount of fluid removed is usually relatively small.

Elimination Enhancement

Amatoxins are dialyzable. However, the low concentration of amatoxins in plasma limits the usefulness of measures to enhance elimination, such as charcoal hemoperfusion and hemodialysis. Case reports associate a favorable outcome with the use of hemoperfusion within 36 hours of ingestion.[92] However, hemoperfusion performed 12–14 hours after ingestion of amatoxin-containing mushrooms eliminated <4% of the estimated absorbed dose of α-amanitin.[34] In 2 patients treated with hemodialysis 23 hours after ingestion of amatoxin and later with charcoal hemoperfusion, analysis of the blood before treatment, after treatment, and in the hemodialysis and hemoperfusion circuits did not detect any α- or β-amanitin.[93] Consequently, there are inadequate pharmacokinetic data to support the routine use of charcoal hemoperfusion or hemodialysis during amatoxin poisoning. The theoretical exception would be a patient with pre-existing renal dysfunction with confirmed amatoxin poisoning seen early in the course of the intoxication, when high concentrations of amatoxins are in the blood.

A review of detoxification techniques involving plasmapheresis suggested that mortality from amatoxin poisoning decreased substantially over the last 20 years following the use of plasmapheresis during the first 24–36 hours of intoxication in combination with supportive care.[94,95] However, there are few pharmacokinetic data or controlled clinical trials to support the use of plasmapheresis. Although glomerular filtration eliminates amatoxins, there is no definitive clinical evidence that forced diuresis enhances the elimination of amatoxins more than generous fluid replacement (i.e., urine flow = 100–200 mL/h).[62] Case reports associated improvement in hepatic function after the use of hemodialysis and the Molecular Adsorbent Recycling System (MARS) during amatoxin-induced hepatic failure,[96] but the role of this technique during *Amanita*-induced liver failure remains to be defined.

Drug Therapy

There is no proven antidote for amatoxin poisoning. Case series document the use of a variety of drugs including the silymarin group, β-lactam antibiotics (penicillin G, ceftazidime), rifampicin, thioctic acid, cimetidine, insulin, human growth hormone, cytochrome c, aucubin (iridoid glucoside isolated from *Aucuba japonica* Thunb.), steroids, and vitamin C during treatment for amatoxin poisoning. However, these drugs are usually administered in combination with other drugs, and there are no controlled clinical trials to document the efficacy of any of these treatments. Thioctic acid (α-lipoic acid) is a coenzyme of the Krebs cycle that has few adverse effects except for hypoglycemia. Although thioctic acid has been used extensively in Eastern Europe since 1968,[97] there are few data to document the efficacy of this substance and studies in animals have not documented the beneficial effect of thioctic acid. Currently, thioctic acid is not recommended for the treatment of amatoxin poisoning, particularly because of associated hypoglycemia.[34]

Penicillin G

In the last 20 years, benzylpenicillin (penicillin G) was the most common drug used during amatoxin poisoning, in part because of the easy availability of benzylpenicillin compared with silibinin.[14] Adverse effects include allergic reactions, hyperkalemia, and electrolyte imbalance. There is very limited evidence to suggest that benzylpenicillin improves the outcome of patients with amatoxin poisoning. In dogs, the intravenous administration of benzylpenicillin 5 hours after the oral administration of sublethal dose of *Amanita phalloides* extract reduced liver inflammation and necrosis, as measured by serum hepatic aminotransferases.[98] The similar improvement of coagulation factors was noted, but the effect was less dramatic. An uncontrolled clinical case series suggested that the administration of intravenous benzylpenicillin within 24–48 hours of amatoxin ingestion may improve outcome.[97] Regression analysis of patients receiving multiple treatments for amatoxin poisoning suggested that the addition of benzylpenicillin treatment improves outcome as measured by decreased mortality, particularly in association with the use of silibinin.[99] However, there is no definitive evidence that the administration of high dose benzylpenicillin (300,000–1,000,000 U/kg/d) improves the outcome of patients with amatoxin poisoning. This drug is not approved by the US Food and Drug Administration (FDA) for the treatment of amatoxin poisonings. Penicillin is a treatment option primarily when silymarin is not available.

Silymarin Complex and Silibinin

Silymarin complex is a mixture of at least four closely related flavonolignans derived from the seeds and fruits of the milk thistle *Silybum marianum* (L.) Gaertn. This biennial herb is a member of the aster family (Compositae), which includes daisies and thistles. Historically, this herb was used for the treatment of liver, spleen, and gallbladder diseases. About 60–70% of this mixture is composed of two diastereomers of silibinin (silybin, CAS No. 22888-70-6) with the remainder consisting of isosilibinin, silydianin, and silychristin.[100] The oral absorption of silymarin is poor with estimated bioavailability of approximately 25–50% and an elimination half-life of about 6 hours.[101] Silibinin is the water-soluble preparation of the active agent in silymarin. Histochemical studies of isolated rat hepatocytes indicate that silymarin and silibinin block the uptake of α-amanitin as well as acting as a free-radical scavenger.[102] Some authors suggest that the use of both silibinin and benzylpenicillin improves the outcome of patients with amatoxin poisoning. In a retrospective, uncontrolled Austrian study, the administration of intravenous silibinin (20–50 mg/kg/d in four divided doses) and penicillin was associated with a favorable outcome in all but one of 18 cases of *Amanita phalloides* ingestion.[103] However, because of the study design and the administration of multiple drugs, the efficacy of silibinin was unclear. As a result of the relatively lack of serious adverse reactions following the administration of silibinin, the use of this compound is frequently recommended for the treatment of amatoxin poisoning despite the lack of controlled studies documenting the efficacy of this compound.[100] In the United States, silymarin is available only as a food supplement. In Europe, silibinin is available as the dihemisuccinate salt. The initial dose of silibinin dihemisuccinate is 5 mg/kg IV over 1 hour followed by a daily infusion of 20 mg/kg for 6 days or until the serum hepatic transaminase concentrations normalize.

Supplemental Care

Because the efficacy of drug therapy remains unproven, early diagnosis and good supportive care is the cornerstone of treatment. Attempts to enhance elimination (e.g., duodenal drainage, forced diuresis, serial activated charcoal) within the first 24 to 30 hours are theoretically beneficial. However, the amount of amatoxin removed is probably small and these procedures may worsen fluid and electrolyte imbalances. The patient should receive sufficient fluids to maintain a urine output of at least 100 mL/h for the first several days after amatoxin ingestion. Initial laboratory evaluation includes complete blood count, platelet count, prothrombin time,

serum electrolytes, serum creatinine and BUN, serum calcium and phosphate, serum bilirubin, serum ammonia, serum alkaline phosphatase, and serum hepatic aminotransferases (ALT, AST). For potential serious ingestions, baseline laboratory tests should include arterial blood gases, serum lactate, fibrinogen, and factor analysis (Factor V, anti-thrombin III). Patients with hepatorenal failure should be admitted to an intensive care setting for careful monitoring of fluid and electrolyte balance, serum glucose, measures of hepatic encephalopathy (serum ammonia and bilirubin concentrations), coagulation parameters, and the development of sepsis. Treatment for hepatic encephalopathy includes oral lactulose (30–45 mL every 6–8 hours), protein restriction, and parenteral nutrition. Cerebral edema is the major cause of death following the development of hepatic encephalopathy, and treatment includes mannitol, elevation of the head to 10°–20°, adjustment of ventilator settings, and fluid restriction. Epidural intracranial pressure monitoring is usually necessary to guide treatment of patients with grade 3–4 hepatic encephalopathy. The efficacy of vitamin K_1 for elevation of the prothrombin time during fulminant hepatic failure is unclear. Fresh frozen plasma (rarely, recombinant human factor VIIa) should be used for evidence of current bleeding or prophylactically for invasive procedures. Prophylactic correction of coagulopathy in a nonbleeding patient is not usually recommended. Serial hemoglobin and stool guaiac tests should be followed for evidence of GI bleeding. The administration of proton pump inhibitors (e.g., omeprazole) should be administered to reduce the risk of GI hemorrhage.

Transplantation

The two surgical options for liver transplantation are orthotopic liver transplantation and auxiliary liver transplantation. Total orthotopic liver transplantation requires long-term immunosuppression to maintain the liver graft. Auxiliary partial liver transplantation is an alternative because some native livers may recover with partial hepatectomy and temporary support.[104] Consequently, the transplanted liver provides temporary assistance until the native liver regenerates. Evaluation of patients with amatoxin poisoning for liver transplantation should be considered whenever fulminant hepatic failure develops. Optimally, transport to a liver transport center should occur prior to progression to stage III–IV hepatic encephalopathy and the development cerebral edema. Therefore, patients with hepatic failure that progresses to stage II hepatic encephalopathy are candidates for liver transplant, particularly children. Factors that favor the need for transplantation include prolonged prothrombin time exceeding twice normal values despite vigorous replacement therapy, hypoglycemia requiring parenteral glucose infusions, and progression beyond stage II hepatic encephalopathy.[105] A retrospective study of 198 patients with amatoxin poisoning using receiver-operating-characteristic and sensitivity-specificity analysis indicated that the presence of a prothrombin index <25% and a serum creatinine >1.2 mg/dl (106 umol/L) between 3–10 days after amatoxin ingestion are highly sensitive and specific predictors of ensuing hepatic failure and the need for liver transplantation.[106] In a study of the criteria for transplantation in amatoxin poisoning, the presence of a prothrombin index <10% (INR ≥ 6) 4 days or more after ingestion was the most reliable criteria for the need for transplantation.[107] Neither the degree of encephalopathy nor elevation of the serum creatinine helped separate fatal from nonfatal *Amanita* intoxication in this study. The total serum bilirubin concentration is a less useful factor for the prediction of the need for transplantation because of the relatively late rise of serum bilirubin during the course of fatal amatoxin poisoning. The degree of serum hepatic aminotransferase elevation does not correlate to the need for liver transplant.

Factor V concentration <10% and inadequate response of the prothrombin time to the administration of clotting factors also indicates a poor prognosis without liver transplantation.[57,108] Case reports suggest that increased prothrombin time and decreased Factor V concentrations rather than coagulation inhibitors (antithrombin III, protein C, protein S) are better markers of the severity of amatoxin-induced liver damage.[109] In this report, Factor V, which began increasing 3–4 days after ingestion, was a better indicator of early hepatic recovery than other coagulation factors (fibrinogen, factors II, VII, X). The rapid clearance of amatoxins from the body within 4 days of ingestion limits any hepatotoxic effects of these compounds on liver transplants[62] or the transplantation of organs from donors dying of amatoxin poisoning.[110]

Chapter 38

FALSE MOREL and GYROMITRIN POISONING

HISTORY

Over 100 years ago Bohm and Kulz isolated an oily substance, called helvellic acid, from mushroom specimens belonging to *Gyromitra esculenta* (Pers.) Fr. (*Helvella esculenta*) that was associated with adverse effects following consumption of this mushroom. Later analysis of helvellic acid indicated that the composition of this substance included primarily nontoxic organic acids. In 1967, List and Luft isolated the main toxin, gyromitrin (*N*-methyl-*N*-formyl hydrazone).[1] Toxicity following ingestion of gyromitrin-containing mushrooms is highly variable, even among family members consuming the same meal.[2] Nevertheless, case reports have associated fatalities with the consumption of this mushroom as early as the 1920s.[3] *Gyromitra esculenta* was the most common cause of mushroom-associated toxicity in Poland after World War II based on epidemiologic data.[4] These data included some fatalities.

MYCOLOGICAL DESCRIPTION

The genus *Gyromitra* belongs to the division Ascomycota (sac fungi), which together share a common sac-like structure called the ascus. This structure contains four to eight ascospores in the sexual stage. Some species of *Gyromitra* are among the most valued mushrooms (i.e., the morels). There are at least eight species of *Gyromitra* in the United States that contain variable amounts of gyromitrin. *Gyromitra esculenta* (false morel, Discinaceae family) contains a relatively high concentration of gyromitrin; poisoning from the consumption of these mushrooms usually occurs as a result of confusion of the false morels with species from the true morel mushroom family (Morchellaceae). *Gyromitra esculenta* differs from true morels by the lack of ribs and cavities (pits) on the irregular, brain-shaped cap. Other *Gyromitra* species of toxicological concern include *G. fastigiate* (Krombh.) Rehm and *G. gigas* (Krombh.) Cooke.[5] Other mushroom species contain gyromitrin including *G. infula* (Schaeff.) Quél.), *Helvella crispa* (Scop.) Fr., *Helvella lacunosa* Afzel., *Leptopodia elastica* (Bull.) Boud., and *Otidea onotica* (Pers.) Fuckel,[6] but human toxicity from the consumption of these mushroom is not well documented in the medical literature.

Common Name: False morel, Turban fungus, Lorchel, Brain Mushroom, Beefsteak Morel, Elephant ears

Scientific Name: *Gyromitra esculenta* (Pers.) Fr.

Mycological Family: Discinaceae

Physical Description: *Gyromitra* species do not possess gills. The medium to large caps (3–12 cm/~1–5 in.) are red-brown to dark-brown with irregularly, deeply-wrinkled, convoluted shape. The whitish stem is relatively short compared with the cap. The genus *Gyromitra* belongs to the division Ascomycota, which contain internal ascospores rather than the external basidiospores that form distinguishing spore prints.

Distribution and Ecology: *Gyromitra esculenta* inhabits Europe and North America with specimens common in Germany and Poland. This mushroom prefers conifer forests with siliceous soils, but specimens of *G. esculenta* are found in the plains.

EXPOSURE

In contrast to amatoxin poisoning, toxicity associated with the ingestion of mushrooms from *Gyromitra esculenta* usually occurs in the spring rather than the fall because the fruiting bodies of *G. esculenta* appear from March to May in the United States and in the beginning of summer in Europe. Reports of gyromitrin poisoning are more common in Central and Eastern Europe compared with Western and Southern Europe.[6] The industrial applications of the gyromitrin metabolite, *N*-methylhydrazine, include its use as a rocket propellant and corrosion inhibitor.

PRINCIPAL TOXINS

Physiochemical Properties

All *Gyromitra* species do not contain gyromitrin, and the gyromitrin concentration varies dramatically even within the same species as a result of variable climatic conditions and other undetermined variables. Consequently, adverse reactions can occur following previous, asymptomatic ingestions of this mushroom.[7] Gyromitrin (acetaldehyde-formyl-methyl-hydrazone, CAS RN: 16568-02-8) is the most toxic of the nine hydrazones isolated from *Gyromitra esculenta*.[8] Structurally, gyromitrin is an aldehyde of *N*-methyl-*N*-formyl hydrazine (MFH) as displayed in Figure 38.1. Following hydrolysis, gyromitrin yields aldehyde and *N*-methyl-*N*-formyl hydrazine (MFH), which further hydrolyzes to *N*-methylhydrazine (MMH, monomethylhydrazine).

Gyromitrin is a relatively unstable, colorless hydrazone that is heat labile, slightly volatile, and water soluble. This compound oxidizes at room temperature to acetaldehyde and *N*-methyl-*N*-formylhydrazine. Long-term dry storage and vigorous boiling removes the toxin from *Gyromitra* mushrooms. However, simple parboiling does not guarantee edibility. At least 10 minutes of boiling, preferably in at least 3 L water/kg mushroom, is necessary to reduce the total *N*-methyl-*N*-formylhydrazone concentration below 1% of the value in fresh mushrooms.[9] The concentration of MMH also decreases during storage of these mushrooms at room temperature with reduction in the MMH concentration up to about 50% during 1–3 weeks of storage[10]

Poisonous Parts

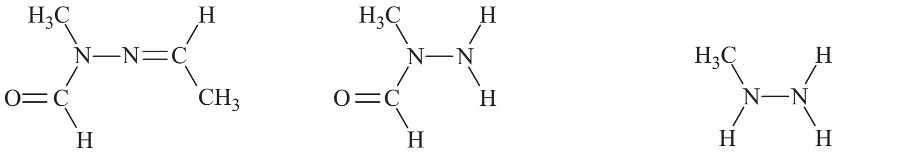
Ingestion of gyromitrin-containing mushrooms produces variable toxicity that depends in part on individual metabolism. The ingestion of cooking juice or liquid that surrounds the mushrooms substantially increases toxicity. Although there are at least eight other hydrazone compounds in *Gyromitra esculenta,* gyromitrin is the most important toxic compound.[8] Thin-layer spectrophotometric studies suggest that the gyromitrin content of the false more (*G. esculenta*) varies substantially in different specimens with a typical range of about 40–730 mg/kg wet weight.[11]

Mechanism of Toxicity

Hydrazine compounds inhibit the enzymatic activation of pyridoxine by reacting with pyridoxal-5-phosphate, resulting in decreased synthesis of GABA and enhanced susceptibility to seizures.[12] However, animal studies suggest that toxic doses of monomethylhydrazine (*N*-methyl hydrazine) cause minimal reduction in GABA formation in the brain;[13] consequently, monomethylhydrazine alone does not account for all of the toxic effects of gyromitrin. The specific metabolite associated with the neurological and gastrointestinal (GI) effects of gyromitrin remains undetermined. In animal studies, a metabolite of gyromitrin (*N*-methyl-*N*-formyl hydrazine) depleted cytochrome P-450 within 8–12 hours of the administration of gyromitrin.[14] Another metabolite (e.g., *N*-methyl hydrazine) of gyromitrin did not exhibit similar hepatotoxicity. Hydrazine compounds are irritating to mucous membranes and the GI tract. In animal studies, the inhalation of hydrazine causes anorexia, weight loss, liver and lung inflammation, and interstitial nephritis.[15] Additionally, hydrazine compounds deplete glutathione in erythrocytes and damage hepatic macromolecules, probably by the formation of free methyl radicals. Case reports associate chronic hydrazine exposure with severe tubular necrosis and mild hepatocellular damage.[16]

DOSE RESPONSE

The clinical response to the ingestion of gyromitrin-containing mushrooms is highly variable, depending on



Gyromitrin **N-methyl-N-formylhydrazine** **Monomethylhydrazine**

FIGURE 38.1. Structure of gyromitrin and metabolites.

a number of factors including individual sensitivity, gyromitrin content of the mushrooms, and amount of gyromitrin removed during food preparation. There is also substantial variation in the response of different animal species to gyromitrin. In an animal study, the no-effect level of gyromitrin for rabbits and chickens varied 10-fold (i.e., 0.5 mg/kg/d and 0.05 mg/kg/d, respectively).[17] Based on these animal studies and the average gyromitrin content of mushrooms from *G. esculenta*, the estimated maximal tolerated dose in adults is 35 μg/kg and the estimated lethal dose in adults is approximately 20–50 mg/kg.[6]

TOXICOKINETICS

Hydrolysis of gyromitrin (acetaldehyde-*N*-formyl-*N*-methylhydrazone) in the acidic conditions of the stomach produces absorbable hydrazine compounds by conversion of gyromitrin to acetaldehyde and *N*-methyl-*N*-formylhydrazine (CAS RN: 758-17-8). The latter compound hydrolyzes to monomethylhydrazine (CAS RN: 60-34-4, methylhydrazine) and more slowly to formic acid.[18] There are few toxicokinetics data on the biotransformation of gyromitrin in humans. In a rodent study, about 25% of the gyromitrin was metabolized to monomethyl hydrazine.[19] Figure 38.1 displays the chemical structure of gyromitrin, *N*-methyl-*N*-formylhydrazine, and monomethylhydrazine.

CLINICAL RESPONSE

Clinical features of gyromitrin poisoning primarily involve gastrointestinal and neurological effects. Ingestions of gyromitrin-containing mushrooms usually produce mild GI symptoms, depending on a variety of variables including preparation techniques and gyromitrin content. The onset of GI symptoms is delayed 2–8 hours up to 2 days, and this delay may be similar to the onset of GI symptoms during amatoxin poisoning.[20] In mild cases, GI symptoms (nausea, vomiting, abdominal pain) may persist for several hours to several days including nonspecific symptoms (headache, fatigue, malaise). Symptoms usually resolve in 2–6 days without sequelae.[21] Some neurological symptoms (tremor, ataxia, nystagmus, dizziness, fatigue, slurred speech) also may occur. In severe cases, coma, seizures, and hepatic failure develop 1–3 days after ingestion complicated by hypoglycemia and hypovolemia.[22] Hemolysis with rhabdomyolysis and renal dysfunction are potential complications of gyromitrin poisoning, but these complications are not well documented in the recent medical literature. Fatalities from hepatorenal failure following the ingestion of gyromitrin-containing mushrooms are rare.[22]

The International Agency for Research on Cancer (IARC) lists gyromitrin as not classifiable with regard to its carcinogenicity in humans (group 3). Following the administration of gyromitrin by intragastric intubation to mice, increased incidences of tumors occurred in the forestomach, clitoral gland, and lung of females and in the preputial gland of males.[23] The lifetime oral administration of *Gyromitra esculenta* mushrooms to Swiss mice produced an increased incidence of tumors of the lung, blood vessels, and forestomach.[24] Although exposure potentially occurs during ingestion of gyromitrin-containing mushrooms, destruction of gyromitrin during cooking limits exposure in humans. Hydrolysis of gyromitrin in the stomach yields the methylating agents *N*-methyl-*N*-formyl hydrazine and *N*-methyl hydrazine. Based on studies in animals, the carcinogenic risk associated with the consumption of mushrooms from *G. esculenta* is small.[25] There are no case reports or epidemiological studies associating the consumption of gyromitrin-containing mushrooms with carcinogenicity.

DIAGNOSTIC TESTING

Chromatographic analytical methods are highly specific and sensitive for the detection of toxins in *Gyromitra esculenta*. Gas-liquid chromatography detects unbound gyromitrin and *N*-methyl-*N*-formyl hydrazine (MFH), but this method does not account for MFH bound to high-molecular-weight compounds. Thin-layer chromatography yields gyromitrin, MRH, and *N*-methyl hydrazine (monomethylhydrazine).[11] Extraction of dried gyromitrin-containing mushrooms with anhydrous solvents does not yield gyromitrin, whereas heating these mushrooms in a sealed tube at 120 °C (248 °F) liberates gyromitrin and *N*-methyl-*N*-formyl hydrazine.[26] Other methods for the quantitation of gyromitrin in mushroom specimens include gas chromatography/mass spectrometry (GC/MS). The limit of quantitation for gyromitrin using GC/MS and the pentafluorobenzoyl derivative of methylhydrazine is approximately 0.3 μg/g dry matter.[27] Potential laboratory abnormalities associated with gyromitrin poisoning include elevated serum hepatic aminotransferases, hypoglycemia, methemoglobinemia, and evidence of hemolysis. Typically, abnormalities of serum hepatic aminotransferases peak about 5 days after ingestion.[21,22]

TREATMENT

Fluid and electrolyte imbalance is the most common complication of serious gyromitrin poisoning. The occurrence of coma or convulsions is extremely rare, and these complications should be treated with the usual

supportive care (e.g., respiratory support, lorazepam or diazepam) and rapid evaluation of blood glucose concentrations. Most patients do not require decontamination because presentation usually occurs >1–2 hours after ingestion. Although no human or animal data are available to guide the therapy of gyromitrin toxicity, the use of a single dose of activated charcoal is a reasonable treatment modality. Pyridoxine (25 mg/kg or 5 g intravenous dose up to a daily adult dose of 15–20 g) has been recommended for serious neurological symptoms (e.g., coma, seizures) of gyromitrin poisoning based on the similarity between gyromitrin and hydrazine toxicity.[28,29] Although some animal studies suggest that the use of pyridoxine may reduce the neurotoxicity of some hydrazine compounds (*N*-methyl hydrazine), these effects are minimal following the administration of other hydrazine compounds (e.g., *N*-methyl-*N*-formyl hydrazine).[30] There are inadequate clinical data to confirm the efficacy of pyridoxine for the treatment of neurotoxicity (seizures, coma) associated with the ingestion of gyromitrin-containing mushrooms.[31] Animal data do not support the efficacy of pyridoxine for the liver abnormalities caused by gyromitrin.[14] There are no clinical data to indicate that the use of methods to enhance elimination improve clinical outcome.

Gyromitrin-induced hepatic encephalopathy requires the same supportive treatment administered following amatoxin poisoning. In severe cases, baseline laboratory analysis of the blood should include a complete blood count, serum electrolytes, creatinine, ammonia, hepatic aminotransferases, and glucose as well as coagulation studies (e.g., prothrombin time). Animal studies suggest that hemoglobinuria may complicate serious gyromitrin toxicity, but there are no recent cases to document the occurrence of this complication in humans. Other suggested treatment regimens with few clinical data include the use of *N*-acetylcysteine and folic acid. Hydrazine compounds inhibit the chemical transformation of folic acid to the active form, folinic acid. Although some authors recommend the daily doses of 20–200 mg folinic acid, there are inadequate clinical data to confirm the efficacy of this drug for gyromitrin poisoning.

Chapter 39

GASTROENTERITIS-PRODUCING MUSHROOMS

EXPOSURE

The rapid onset of gastroenteritis is the most common adverse response to the ingestion of mushrooms. Most of the cases of mushroom-induced gastroenteritis are mild, and many of these cases are not reported in the medical literature. Despite food preparation techniques, a large group of mushrooms are capable of producing gastroenteritis as listed in Table 39.1.[1] The consumption of a variety of mushrooms can produce gastroenteritis when improperly prepared including *Amanita rubescens* var. *rubescens* Pers., *Amanita spissa* (Fr.) P. Kumm., *Amanita strobiliformis* (Paulet ex Vittad.) Bertill., *Amanita vaginata* (Bull.) Lam. var. *vaginata, Boletus queletii* Schulzer (*Boletus erythropus*), *Boletus luridus* Schaeff., *Choiromyces meandriformis* Vittad., and *Entoloma clypeatum* (L.) P. Kumm., pungent *Lactarius* and *Russula* species, *Clitocybe nebularis (Batsch)* Quél., *Lepista nuda* (Bull.) Cooke, *Paxillus involutus* (Batsch) Fr., *Russula olivacea* (Schaeff.) Fr. and *Sarcosphaera coronaria* (Jacq.) J. Schröt. (*S. crassa*).[1] These species are edible when properly prepared. In a small segment (<2%) of the population, individuals possess trehalase disaccharidase deficiency. Ingestion of trehalose-containing mushrooms (e.g., *Agaricus bisporus* (J.E. Lange) Pilát, *Boletus edulis* Bull.) by these susceptible patients causes the onset of diarrhea and abdominal cramps as a result of the failure to absorb trehalose through the intestinal brush-border.[2,3] Illudin S derivatives (i.e., irofulven and related compounds) are experimental chemotherapeutic agents for advanced solid tumors.[4,5]

PRINCIPAL TOXINS

Physiochemical Properties

There are few data on the chemical toxins associated with most cases of mushroom-induced gastroenteritis. Although many fungi contain terpenoid compounds capable of producing gastrointestinal (GI) effects, the chemical constituents of most GI toxins associated with the ingestion of mushrooms remains undetermined. The blood-red Cortinarius [*Cortinarius sanguineus* (Wulfen) Fr.] contains a variety of anthraquinone compounds including emodin, dermocybin, dermorubin, physcion, endocrocin, dermolutein, 5-chlorodermorubin, emodin-1-β-D-glucopyranoside, dermocybin-1-β-D-glucopyranoside, 7-chloroemodin, 5,7-dichloroemodin, 5,7-dichloroendocrocin, 4-hydroxyaustrocorticone and austrocorticone.[6] Anthraquinone compounds exhibit prominent cathartic properties. Several of the anthraquinone compounds in *Cortinarius sanguineus* are mutagenic in *in vitro* assays including the most prominent anthraquinone compound, emodin.[7] The sulfur tuft [*Hypholoma fasciculare* (Huds.) P. Kumm.] has been associated with mushroom poisoning,[8,9] but the toxic constituents have not been identified. Analytical studies indicate that this mushroom species contains sesquiterpenoid compounds (fascicularones A and B)[10,11] as well as potent calmodulin antagonists (fasciculic acids A, B, and C).[12,13] The clinical significance of these compounds remains undetermined.

The jack-o-lantern [*Omphalotus illudens* (Schwein.) Bresinsky & Besl] contains the sesquiterpene com-

TABLE 39.1. Common Gastroenteritis-Producing Mushroom Species*

Genus	Species	Occurrence	Distinguishing Features
Agaricus	*hondensis* Murrill	Summer, fall	White to gray-brown cap with brown spore print and negative amyloid reaction
Agaricus	*xanthodermus* Genev.	Forests and occasionally meadows and gardens: summer to fall	Intense yellow coloration when flesh rubbed with phenol-like smell; forms large fairy rings in deciduous forests
Boletus	*satanas* Lenz	Warm climates underneath oak trees: July to September	Large pale cap (6–25 cm/~2–10 in.) and short stalk with swollen base; flesh has unpleasant smell and blue discoloration after trauma
Chlorophyllum	*molybdites* (G. Mey.) Massee *(Lepiota molybdites)*	Common mushroom found in the United States, Central and South America, Japan, Central Africa, Australia: Late summer, early fall	Large (20–25 cm), white, scaly cap with free, white-green gills, green spore print and negative amyloid reaction; No volva (cup)
Cortinarius	*sanguineus* *(Dermocybe sanguineus)*	Wet, boggy areas of conifer forests	Deep blood to wine-red flesh with rust-brown spore print
Entoloma	*sinuatum* (Bull.) P. Kumm. *(E. lividum)*	Deciduous forests in rows or rings: Summer to fall	Large, whitish to light ochre fungus with red-ochre gills on mature specimens; spore print salmon-pink
Hebeloma	*crustuliniforme* (Bull.) Quél.	Common in large groups or rings underneath trees	Medium-sized with pale, ochre curved cap with whitish border and brown spore mass; yellow to olive-brown spore print
Hypholoma	*fasciculare* (Huds.) P. Kumm. *(Naematoloma fasciculare)*	Appears as large tufts on stumps of conifer and deciduous trees	Sulfur yellow to green gills that become grey-lilac as the specimen matures; light yellowish cap with grey to brown-violet spore mass
Lactarius	*helvus* (Fr.) Fr.	Humus-rich soils beneath birch, pine, and spruce trees: Summer to fall	Large, dry, velvety cap with brown flesh to yellow-ochre color
Megacollybia	*platyphylla* (Pers.) Kotl. & Pouzar *(Tricholomopsis platyphylla)*	Large mushroom on wood of deciduous trees joined by mycelial strands	Grey to dark brown cap with white spore mass
Omphalotus	*illudens* (Schwein.) Bresinsky & Besl *(Clitocybe illudens)*	Wood-associated fungus near olive, chestnut, and oak trees, particularly in warm climates	Orange fungus with large red-brown cap and yellowish white spore mass
Ramaria[a]	*formosa* (Pers.) Quél.	On ground in deciduous forests near beech trees: August, September	Large, multicolored coral fungus with pink to salmon base and yellow tips. Spore mass is ochre to yellow with red-brown spore print.
Russula	*emetica* (Schaeff.) Pers.	Wet boggy forests and some drier deciduous and conifer forests	Pungent-tasting mushroom with large (5–10 cm/2–4 in.) blood to cherry-red cap and white spore print
Scleroderma	*citrinum* Pers.	Widespread in deciduous and conifer forests and the edges of woodlands: Summer to late fall	Thick, solid fruiting body that has an uneven, cream-yellow to ochre surface, known as poison puffball or common earth-ball; brown spore print
Tricholoma	*pardinum* Quél	Decomposes later in conifer and deciduous forests	Large mushroom with white spores and white, sinuate gills and grey, scaly cap

*This list is a partial one because of the large number of mushroom species capable to producing gastroenteritis and the lack of documentation in the medical literature.

[a]A similar species (e.g., *Ramaria pallida* Maire) is associated with gastroenteritis in Germany.

pound, iludin S, which is responsible for some of the GI effects from ingestion of this mushroom; this compound also has some antiviral properties.[14] In rodent studies, illudin S is a cytotoxic substance,[15] and the oral administration of illudin S causes inflammation and edema in the stomach and proximal small bowel as well as erosion and edema of the gastric mucosa.[16] *Boletus satanas* Lenz contains a nucleoside triphosphate phosphatase (bolesatine), which inhibits protein synthesis via the hydrolysis of guanosine-5′-triphosphate (GTP).[17] The clinical significance of this compound as a GI irritant requires more study. *Chlorophyllum molybdites* contains a partially heat labile, high-molecular-weight toxin based on animal studies.[18] However, the exact identity of this toxin is unknown.

Mechanism of Toxicity

Because most GI irritants remain unidentified, most mechanisms of action are also unknown. Although some mushrooms [e.g., *Amanita muscaria* (L.) Hook. or fly agaric] accumulate heavy metals (e.g., mercury) with bioconcentration factors up to 100–200, analysis of wild mushrooms for mercury indicate that mercury toxicity is unlikely following the normal consumption of mushrooms.[19]

DOSE RESPONSE

Predicting toxicity following the ingestion of gastroenteritis-producing mushrooms is complicated by variable responses. Some people consume varieties of gastroenteritis-producing mushrooms without effects, whereas other individuals develop gastroenteritis after previously eating similar mushrooms without adverse effects.[20] Similarly, some family members eating the same meal develop GI symptoms, while other family members do not. Factors that affect the severity of GI effects include geographic variations, individual sensitivity, food preparation techniques, and variability in toxin content.

CLINICAL RESPONSE

Because of the paucity of human data, precise descriptions of the gastrointestinal syndrome associated with each gastroenteritis-producing species are not well-documented. In general, the latent period following the ingestion of gastroenteritis-producing mushrooms is short with an average of 15 minutes to a few hours.[21] GI symptoms include nausea, vomiting, abdominal cramps, and profuse, watery diarrhea that may become blood-tinged.[22,23] Other non-specific symptoms include chills, myalgias, headache, and fatigue.[24] Occasionally, cholinergic-like symptoms develop including diaphoresis, lacrimation, blurred vision, and salivation, particularly following ingestion of European species of gastroenteritis-producing mushrooms.[25] The clinical features of this syndrome are self-limited with resolution within 24–48 hours without sequelae. Rarely, the GI symptoms are severe enough to produce clinically significant fluid and electrolyte imbalance, particularly in elderly patients with cardiovascular disease and young children.[26,27] The presence of fever suggests a secondary infectious process (e.g., pericolonic abscess).[20]

DIAGNOSTIC TESTING

In most cases, diagnostic testing is not available to identify the toxins associated with gastroenteritis-producing mushrooms. In serious cases, evaluation of serum electrolytes, serum creatinine, and serum BUN help determine the severity of the poisoning. Transient leukocytosis, proteinuria, microscopic hematuria, and fecal leukocytes may occur during the acute phase of gastroenteritis.[22] Rarely, minimal elevations of serum hepatic aminotransferases occur following the ingestion of *Omphalotus illudens* (Schwein.) Bresinsky & Besl (jack o’ lantern), but these values quickly return to normal without liver dysfunction (i.e., prolonged prothrombin time).[28] A single case report associated profuse rectal bleeding with thrombocytopenia, mild hypofibrinogenemia, and slightly prolonged partial thromboplastin time after the ingestion of a portion of a raw specimen of *Chlorophyllum molybdites* (G. Mey.) Massee.[29] There was no evidence of hepatocellular damage (i.e., normal serum bilirubin and hepatic aminotransferases), and the patient recovered with supportive care. Methods are available to identify spores (e.g., *Chlorophyllum molybdites*) in stools and vomitus after sample filtration and staining with 1% acid fuchsin.[30]

TREATMENT

Treatment primarily involves the evaluation of fluid and electrolyte status. The most important part of patient care is the differentiation of gastroenteritis-producing mushrooms from amatoxin-containing mushrooms. Although both types can be ingested at the same time, the rapid onset of GI symptoms favors the ingestion of gastroenteritis-producing mushrooms. Severe cases should be monitored for electrolyte abnormalities (e.g., hypokalemia) and fluid depletion. Rarely, vasopressors and respiratory support are necessary. Most symptoms resolve within 24–48 hours. If the ingestion of amatoxin-containing mushrooms is excluded, patients with gastroenteritis may be discharged after control of the vomiting

and diarrhea with antiemetics and antidiarrheal agents as needed.

Chapter 40

INKY CAP and COPRINE TOXICITY

[*Coprinus atramentarius* (Bull.) Fr.]

HISTORY

The mushrooms of *Coprinus atramentarius* (Bull.) Fr. (ink cap) contain a protoxin, coprine, which following metabolism interacts with ethanol to produce a disulfiram-like reaction. In the early 1900s, amateur French mycologists discovered this mushroom–ethanol interaction after developing coprine toxicity following the consumption of ethanol and a meal containing *Coprinus atramentarius* mushrooms.[1] Later reports from France, Germany, and the United States confirmed the toxic effects of the combined consumption of *Coprinus atramentarius* mushrooms and ethanol.[2,3] Ingestion of ethanol before or concurrently with consumption of this otherwise edible species did not cause an adverse reaction.

MYCOLOGICAL DESCRIPTION

Although some related *Coprinus* species probably contain coprine including *C. acuminatus* (Romagn.) P.D. Orton, *C. romagnesianus* Singer, *C. quadrifidus* Peck, *C. variegatus* Peck, *C. comatus* (O.F. Müll.) Gray, *C. atramentarius* is the only species documented to contain sufficient amounts of coprine to produce human toxicity.[1] Other unrelated species are associated with a disulfiram-like reaction including *Boletus luridus* Schaeff., (club-footed Clitocybe), *Pholiota squarrosa* (Weigel) P. Kumm., *Tricholoma equestre* (L.) P. Kumm. (*T. auratum*), and *Ptychoverpa bohemica* (Krombh.) Boud., *Verpa bohemica,* and *Clitocybe clavipes* (Pers.) P. Kumm.,[4] but the relationship of coprine to these symptoms is not well defined.[5]

Common Name: Ink cap, Tipler's Bane

Scientific Name: *Coprinus atramentarius* (Bull.) Fr.

Mycological Family: Coprinaceae

Physical Description: This species has a moderately large (3–7 cm/~13 in.), oblong cap with a grey to grey-brown top covered with small brown scales. The margin is sulcate-folded over the stalk, and immature gills are white, but they rapidly turn black during maturity. The spore print is black-brown to black. The stem is lighter than the cap and young specimens occasionally have a ring in the lower portion. The common name "inky cap" derives from the propensity of the gills to dissolve into a black fluid during aging.

Distribution and Ecology: *C. atramentarius* is a common fungus that inhabits several continents (e.g., Europe, North America) in a variety of locations including open fields, waste areas, meadows, gardens, and thickets.

EXPOSURE

Coprinus mushrooms are common in autumn, but the fruiting body may also appear in spring and summer. Coprine was investigated as a natural substitute for disulfiram, but the mutagenic and gonadotoxic properties of this compound in studies of experimental animals prevented the commercial use of coprine.[6]

PRINCIPAL TOXINS

Physiochemical Properties

Mushrooms from *C. atramentarius* do not contain disulfiram or calcium cyanamide.[7] The principal active constituent of *C. atramentarius* is coprine, but the lack of activity of this compound when administered to experimental animals indicates that the actual toxin is a metabolite of coprine. Coprine [N^5-(hydroxy-1 cyclopropyl) L-glutamine, CAS RN: 58919-61-2] is a derivative of glutamine with an empirical formula of $C_8H_{14}N_2O_4$. Figure 40.1 displays the chemical structure of coprine. This compound is water soluble and in neutral solutions heat-resistant. Coprine does not inhibit aldehyde dehydrogenase *in vitro*.

Poisonous Parts

The average coprine concentration in frozen specimens of *C. atramentarius* was approximately 160 mg/kg with young specimens containing about 50% of the coprine present in mature specimens. Frying or boiling does not significantly affect the concentration of coprine.[1]

Mechanism of Toxicity

The consumption of coprine-containing mushrooms produces an elevation of acetaldehyde concentrations as a result of the inhibition of aldehyde dehydrogenase. Coprine undergoes hydrolysis by an enzyme with glutaminase-like properties. The resulting hemiaminal compound (1-aminocyclopropanol) yields highly reactive species that form a saturable, reversible enzyme-inhibiting complex. This compound inactivates aldehyde dehydrogenase and blocks the oxidation of acetaldehyde.[8] *In vitro* studies indicate that 1-aminocyclopropanol produces much greater inhibition of aldehyde dehydrogenase activity than coprine.[9] As a result of the blockade of acetaldehyde oxidation, acetaldehyde concentrations increase substantially. However, the exact mechanism of toxicity remains unclear because during experimental studies elevated acetaldehyde concentrations alone do not reproduce the toxicity associated with the ingestion of coprine-containing mushrooms or the disulfiram-ethanol reaction.[10] In contrast to disulfiram, the administration of coprine to experimental animals does not inhibit dopamine decarboxylase.[11]

DOSE RESPONSE

In experimental animals administered coprine without ethanol, the oral toxicity of coprine is low with a LD_{50} of about 1,500 mg/kg.[6] The intensity of the disulfiram-like reaction depends on several factors including the dose of coprine, the amount of ethanol consumed, individual sensitivity, and the time between *Coprinus atramentarius* ingestion and ethanol consumption.

TOXICOKINETICS

Following absorption, coprine undergoes enzymatic hydrolysis of the amide bond to form the hemiaminal compound, 1-aminocyclopropanol (CAS RN: 54376-44-2). This reaction yields a highly reactive species, possibly a cyclopropyliminium intermediate, which interacts with aldehyde dehydrogenase to block the oxidation of acetaldehyde. Animal studies indicate that 1-aminocyclopropanol exerts potent inhibition of aldehyde dehydrogenase *in vitro* and *in vivo*, whereas the administration of coprine has no effect on rat liver aldehyde dehydrogenase *in vitro*.[12] Consequently, 1-aminocyclopropanol is probably the toxic metabolite of coprine. Figure 40.2 displays the chemical structure of 1-aminocyclopropanol.

CLINICAL RESPONSE

Sensitivity to ethanol begins as soon as 15 minutes–2 hours (average, 3–6 hours) after the consumption of *Coprinus atramentarius* mushrooms and may persist up to 48–72 hours. Symptoms of the disulfiram-like reaction in patients sensitized to ethanol by the consumption of *Coprinus atramentarius* mushrooms include headache, facial flushing, paresthesias, metallic taste in mouth, lightheadedness, vomiting, palpitations, tachycardia, diaphoresis, and chest pain. Diarrhea and abdominal pain are unusual. The intensity of symptoms depends

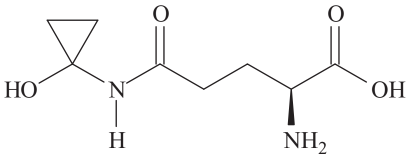

FIGURE 40.1. Chemical structure of coprine.

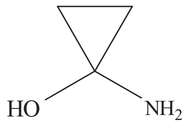

FIGURE 40.2. Chemical structure of the probable toxic metabolite, 1-aminocyclopropanol.

on the absorbed dose of coprine (e.g., food preparation techniques) and ethanol. Other factors include individual sensitivity and the length of time between ethanol consumption and the ingestion of *C. atramentarius* mushrooms. Symptoms of coprine toxicity are usually mild and brief with resolution occurring rapidly (minutes to several hours) without complications. Documented complications during this disulfiram-like reaction include an esophageal rupture confirmed by surgery[13] and the onset of atrial fibrillation in a previously healthy 37-year-old man that resolved spontaneously within 60 hours.[14] Shock, metabolic acidosis, life-threatening cardiac dysrhythmias, and myocardial infarction are complications of the disulfiram-ethanol reaction, but these serious adverse reactions are not well documented following the ingestion of coprine-containing mushrooms and ethanol. Fatalities after the ingestion of *Coprinus atramentarius* are also not well documented.

Coprine and the closely related compound, benzcoprine [CAS RN: 63805-80-1, N-(1-ethoxycyclopropyl)-benzamide], were tested in animals as a natural substitute for disulfiram. Animal studies indicated that chronic consumption of coprine produced bone marrow depression, lymphocytopenia, and reduced testicular weights due to the alkylating effects of coprine on germ cells.[6] However, there are no well documented reports of chronic toxicity resulting from the ingestion of *Coprinus atramentarius*.

DIAGNOSTIC TESTING

There are no biomarkers of coprine toxicity other than the determination of coprine by thin layer chromatography. There are no specific laboratory abnormalities associated with coprine poisoning. Most patients present with mild symptoms that are not associated with clinically significant laboratory abnormalities.

TREATMENT

The treatment of coprine toxicity is supportive, similar to the disulfiram-ethanol reaction. Although the clinical features of coprine toxicity are usually mild, potentially serious complications include hypotension and cardiac dysrhythmias based on the effects of disulfiram and ethanol. Patients with abnormal vital sign or pre-existing cardiovascular disease should receive cardiac monitoring, pulse oximetry, and an intravenous line along with fluids as necessary. Theoretically, hypotensive patients, who do not respond to fluid replacement, should receive a direct-acting vasopressor (e.g., norepinephrine) because norepinephrine stores may be depleted in the coprine-ethanol syndrome similar to the disulfiram-ethanol interaction. Decontamination measures are usually not necessary because of frequent vomiting and the rapid absorption of ethanol. There are no antidotes and no methods to enhance the elimination of coprine or the toxic metabolite. Correction of fluid and electrolyte imbalance and treatment of anxiety with benzodiazepines (lorazepam, diazepam) are the most important supportive measures. Patients may be discharged when comfortable. They should avoid all ethanol-containing products (e.g., ethanol-containing cold remedies and medical elixirs, alcoholic beverages) for at least 48 hours after the onset of symptoms. Theoretically, metoclopramide and odansetron are the antiemetics of choice because the α-adrenergic-blocking properties of phenothiazine antiemetics potentially exacerbate hypotension, but there are inadequate clinical data to confirm the clinical significance of this potential adverse effect.

Chapter 41

ISOXAZOLE-CONTAINING MUSHROOMS and PANTHERINA SYNDROME (*Amanita muscaria, Amanita pantherina*)

HISTORY

Polychromatic rock paintings from the Paleolithic age (9000–7000 BC) contained images of *Amanita* mushrooms, which resembled *Amanita muscaria*.[1] DNA studies suggest that *A. muscaria* originated in Eurasia and migrated across land bridges to North America.[2] The use of psychoactive mushrooms from various genera (e.g., *Psilocybe, Conocybe, Gymnopilus, Panaeolus*) in Mexican and Central American religious rites continued into the middle of the 20th century. However, in contrast to the hallucinogenic mushrooms, fly agaric [*Amanita muscaria* (L.) Hook] has not been a common object of religious veneration.[3] In the Mayan civilization, legends linked *A. muscaria* with the thunderbolt.[4] *Amanita muscaria* and *Amanita pantherina* (DC.) Krombh. are the two major North American and European mushroom species that contain psychoactive isoxazole compounds.

MYCOLOGICAL DESCRIPTION

The Pantherina syndrome is associated with the ingestion of ibotenic- and/or muscimol-containing *Amanita* mushrooms, such as *A. aprica* J. Lindgr. and Tulloss, *A. gemmata* (Fr.) Bertill., *A. muscaria* (L.) Hook, *A. pantherina* (DC.) Krombh. and *A. regalis* (Fr.) Michael.[5,6] Like amatoxin-containing *Amanita* species, *Amanita muscaria* and *Amanita pantherina* possess an annulus (ring), white spore print, and free lamellae (gills). In contrast to the hepatotoxic *Amanita* species, *A. muscaria* and *A. pantherina* have a universal veil that remains on the cap in the form of scales. Rather than a cup, one or more verrucose zones encircle the bottom of the stalk. The spores of *Amanita muscaria* and *Amanita pantherina* are nonamyloid.

Common Name: Fly Agaric, Fly-Poison Agaric, False Orange, Scarlet Fly Cup, and Soma

Scientific Name: *Amanita muscaria* (L.) Hook

Mycological Family: Amanitaceae

Physical Description: This large mushroom has a bright red cap (5–15 cm/~2–6 in.) with large white conical scales. The white gills are free from the white stalk, which contains a hanging ring below the cap. Several warty rings encircle the base of the stalk, and warts can extend over the top of the cap. Figure 41.1 displays specimens of fly agaric.

Distribution and Ecology: *A. muscaria* grows in deciduous and conifer forests throughout several continents, particularly under spruce, birch, and pine trees during summer and autumn.

Common Name: The Panther, Panther Cap, Panther Agaric, Panther Amanita, False Blusher

Scientific Name: *Amanita pantherina* (DC.) Krombh.

Mycological Family: Amanitaceae

Physical Description: This mushroom has a distinctive cup-shaped bulb at the base of the stalk along with a brown cap (5–10 cm/~2–4 in.) that contains white scales. The margin of the cap is striped, and

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

FIGURE 41.1. Fly agaric [*Amanita muscaria* (L.) Hook]. © 2006 Rune Midtgaard. See color insert.

the stalk has a fine ring just below the cap. The gills and stalk are white and the spore print is white.

Distribution and Ecology: *Amanita pantherina* inhabits a smaller geographic area compared with *A. muscaria*, but occasionally *A. pantherina* is abundant in local deciduous or conifer forests. *Amanita pantherina* appears most commonly during the rainy seasons of spring, summer, and fall.

EXPOSURE

Accidental ingestion of *Amanita muscaria* is unusual because of its distinctive features, and most ingestions of this mushroom occur when patients intentionally seek these mushrooms for their psychoactive properties.[7] Misidentification of *Amanita muscaria* for *Amanita caesarea* (Scop.) Pers. and of *Amanita pantherina* for *Amanita rubescens* var. *rubescens* Pers. also occurs. *Amanita pantherina* is more easily confused with edible *Amanita* species compared with *A. muscaria*.

PRINCIPAL TOXINS

Physiochemical Properties

The principal biologically active compounds in *Amanita muscaria* and *Amanita pantherina* probably are the

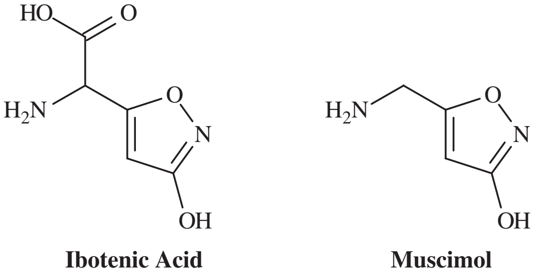

FIGURE 41.2. Chemical structures of muscimol and ibotenic acid.

water soluble isoxazole compounds, ibotenic acid (α-amino-3-hydroxy-5-isoxazoloacetic acid, CAS RN: 2552-55-8) and muscimol (5—aminomethyl-3-hydroxy-isoxazole, CAS RN: 2763-96-4). Figure 41.2 displays the chemical structure of these isoxazole compounds. Other active compounds (e.g., muscazone) may also contribute to the effects of these mushrooms.[1] The fruiting bodies of these *Amanita* species contain substantially more ibotenic acid than muscimol. However, psychotropic effects probably result from muscimol, which is formed from the decarboxylation of ibotenic acid during food preparation and digestion in the gastrointestinal tract. Muscarine does not contribute to the toxic effects of these mushrooms.[8] Muscazone (α-amino-2,3-dihydro-2-oxooxazole-5-oacetic acid, CAS RN: 2255-39-2) is the lactame isomer of muscimol that probably exhibits minor pharmacological activity compared with muscimol.[1] Muscarufin is a terphenylquinone compound that is probably responsible for the bright color of *Amanita muscaria*. Specimens of *A. muscaria* accumulate relatively high concentrations of heavy metals including vanadium, cadmium, and selenium. Amavadin is a pale blue vanadium complex formed in *A. muscaria*, which may concentrate vanadium in concentrations up to 200 ppm.[9] The extracts from *A. muscaria* have weak insecticidal properties. Specimens of *A. pantherina* also contain two amino acids (stizolobic acid, stizolobinic acid), which probably are not toxicologically significant.[10]

Poisonous Parts

Chromatographic studies indicate that ibotenic acid and muscimol occur in *A. muscaria, A. pantherina*, A. *cothurnata* G.F. Atk., and to a lesser extent in *A. gemmata*.[6] The concentrations of isoxazole compounds vary both between these *Amanita* species and within individual specimens. The concentrations of isoxazole compounds are relatively high in the yellow tissue beneath the red cuticle and in the white flesh and gills compared with the stalk.[11,12] In a study of fresh specimens of *Amanita muscaria*, the concentrations of ibotenic acid and

muscimol were higher in caps (990 µg/g fresh weight and 380 µg/g fresh weight, respectively) than in the stalks (230 µg/g fresh weight and 80 µg/g fresh weight, respectively).[13] Table 41.1 lists the content of ibotenic acid and muscimol in samples of mushrooms purchased at Japanese smoke shops through the Internet.[14] The concentrations of these compounds in the stalks were dramatically lower than the caps with these compounds being undetectable in some stalks. This study also suggested that some purported extracts of *A. muscaria* actually contain psychoactive tryptamines (harmaline, 5-methoxy-*N,N*-diisopropyltryptamine) rather than ibotenic acid or muscimol. The concentration of muscarine in specimens of *A. muscaria* is several orders of magnitude below the muscarine concentrations found in certain *Inocybe* and *Clitocybe* species.

Mechanism of Toxicity

Ibotenic acid and muscimol are part of a naturally occurring group of excitatory amino acids that include domoic acid, tricholomic acid, kainic acid, and quisqualic acid. Ibotenic acid and muscimol are conformationally restricted derivatives of glutamic acid and γ-aminobutyric acid (GABA), respectively. In animal models, muscimol binds to GABA-receptors, whereas ibotenic acid affects glutamic acid receptors by changing membrane permeability and resting potential.[15,16] Specifically, ibotenic acid acts on inhibitory glutamate receptors, which are closely related to ionotropic glycine and gamma-aminobutyric acid (GABA) receptors.[17] Glutamic acid is a major excitatory neurotransmitter in mammalian central nervous systems. Muscimol is an inhibitor of neuronal and glial GABA uptake and a substrate for the GABA-metabolizing enzyme, GABA transaminase. In rodent models, muscimol is about five times more toxic than ibotenic acid.[18] *In vitro* studies of mouse brain homogenates indicate that ibotenic acid can undergo decarboxylation to muscimol in the brain.[19] Muscimol probably accounts for most of the central nervous system effects of these mushrooms due to the decarboxylation of ibotenic acid to muscimol.[1]

DOSE RESPONSE

Predicting toxicity based on a history of the amount ingested is difficult because of variation in the ibotenic acid and muscimol concentrations in these species as well as the preparation method and individual sensitivities. The concentration of toxins in these species is highly variable and food preparation may eliminate some, but not all of the toxins. Some people eat portions of *A. muscaria* after a variety of preparation techniques including consuming the entire fruiting body of *A. muscaria* after peeling the cuticle (outer membrane) from the cap and discarding the cooking water, sautéing the mushroom in brine after boiling and removing the cooking water, and drying and smoking the cap after peeling off the cuticle.[1] Based on an estimated average isoxazole content of 0.2%, 100 g of fresh psychoactive *Amanita muscaria* mushrooms contain sufficient muscimol equivalents (i.e., 12 mg) to cause mild intoxication (lightheadedness, ataxia, mood elevation, poor coordination).[20] Other authors estimated that the average size fruiting body of *A. muscaria* (60–70 g) contains up to 70 mg ibotenic acid (i.e., muscimol equivalents).[1] Based on the concentrations of ibotenic acid and muscimol in *Amanita* caps listed in Table 41.1, central nervous system effects develop after an estimated dose of about 7–30 g of *A. muscaria* caps or approximately 4–5 g of *A. pantherina* caps.[14]

TOXICOKINETICS

Based on the rapid onset of central nervous system symptoms after ingestion of these mushrooms, gastrointestinal absorption is rapid (i.e., 30–60 minutes). Both ibotenic acid and muscimol cross the blood–brain barrier. Decarboxylation of ibotenic acid (pantherin, agarin) produces muscimol (pyroibotenic acid). Renal excretion of muscimol is rapid with detectable quantities of unchanged muscimol appearing in the urine within 1 hour after ingestion.

CLINICAL RESPONSE

The clinical features of the pantherina syndrome are similar to ethanol intoxication. Initial symptoms begin about 30 minutes to a few hours after ingestion.[21] Toxic effects primarily involve the central nervous system manifest by euphoria, spacial distortion, increased sensitivity to visual and auditory stimuli, mydriasis, anxiety,

depression, disorientation, ataxia, agitation, blurred vision, fasciculations, tremor, and convulsions.[22,23] Isoxazole compounds produce alterations in visual perception rather than well-formed hallucinations associated with the consumption of indole derivatives (psilocybin, psilocin). Consciousness may alternate between periods of severe lethargy and periods of agitation (screaming, confusion, incoherence, irritability). A deep sleep with vivid dreams often occurs before complete recovery. Vomiting is unusual, and classic features of anticholinergic or cholinergic intoxication do not occur.[24]

Symptoms are generally mild and self-limited, particularly for *A. pantherina* and *A. regalis*, with resolution occurring in 4–24 hours without sequelae.[25,26] Residual headaches may persist in some patients for several days. Respiratory depression does not usually occur unless the patient is heavily sedated with anticonvulsants for seizure activity. A 48-year-old man developed vomiting, seizures, and coma after ingesting a plate of mushrooms that included *A. muscaria*.[27] He awoke 10 hours after ingestion with a paranoid psychosis manifest by visual and auditory alterations. His mental status returned to baseline after 5 days.

DIAGNOSTIC TESTING

Analytical procedures for the detection of isoxazole compounds include paper chromatography,[28] gas chromatography/mass spectrometry (GC/MS),[14,29] high performance liquid chromatography (HPLC), high performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS),[30] and high performance thin layer chromatography (HPTLC). The latter method quantitates muscimol equivalents because the extraction procedure with formic acid facilitates the decarboxylation of ibotenic acid to muscimol. Ion-interaction HPLC allows the separation of ibotenic acid and muscimol with detection limits of 18 μg/L (ibotenic acid) and 30 μg/L (muscimol).[13] Muscimol and ibotenic acid are stable in dry mushroom specimens stored at room temperature for at least 90 days. Clinically significant laboratory changes are not usually associated with ingestion of these mushrooms.

TREATMENT

Treatment is supportive. Respiratory depression is not usually a feature of the pantherina syndrome, although intubation may be necessary following the treatment of seizures. Convulsions usually respond to benzodiazepines (lorazepam, diazepam). Decontamination measures are usually unnecessary. Most patients require only observation; drug therapy (atropine, physostigmine) is not indicated. Agitated patients should be placed in a quiet environment with monitoring of behavior by relatives or close friends. The administration of benzodiazepines (lorazepam, diazepam) may be necessary for severely agitated patients.

Chapter 42

MUSCARINE-CONTAINING MUSHROOMS and MUSCARINE TOXICITY
(*Clitocybe* and *Inocybe* Species)

HISTORY

In 1869, Schmiedeberg and Koppe isolated an impure compound from the Fly Agaric [*Amanita muscaria* (L.) Hook] that they believed was the principal toxin in this mushroom.[1] Almost a century later in 1954, this alkaloid was identified as muscarine by Eugster and Waser.[2] However, muscarine was a minor constituent of the Fly Agaric; muscarine was not the cause of the pantherina syndrome associated with this mushroom. Ingestions of muscarine-containing mushroom species (*Clitocybe* spp., *Inocybe* spp.) produce a syndrome characterized by mild cholinergic excess.[3] Serious toxicity is rare, in part, because of limited accessibility to many toxic species, the poor bioavailability of ingested muscarine, and undesirable physical characteristics (small, malodorous) of muscarine-containing mushrooms.

MYCOLOGICAL DESCRIPTION

Table 42.1 lists muscarine-containing mushrooms, primarily in the genera *Clitocybe* and *Inocybe*. The muscarine syndrome is not associated with the ingestion of mushrooms from the Fly Agaric [*Amanita muscaria* (L.) Hook]. The identification of muscarine-containing species frequently requires an expert mycologist because they often occur close to other similar-appearing fungi. *Inocybe* species are small to large fungi with glabrous, brown spores and radially striate caps. *Inocybe erubescens* A. Blytt (*Inocybe patouillardii* Bres., red-staining Inocybe) is the most common *Inocybe* species associated with toxicity in Europe.[1] They have white-tan to gray caps and fleshy central stalks. Most *Clitocybe* species are small, brown mushrooms with conical, fibrillose caps and adnate, whitish to tobacco brown gills. The toxic species, *Clitocybe dealbata* (Sowerby) Gillet, is whitish.[4] *Clitocybe* is a widely distributed genus that occasionally inhabits lawns and parks. *Inocybe* species occur in oak and pine woods.

Common Name: Ivory Clitocybe, White Clitocybe, Sweat-producing Clitocybe

Scientific Name: *Clitocybe dealbata* (Sowerby) Gillet

Mycological Family: Tricholomataceae

Physical Description: A small, white fungus with funnel-shaped caps (2.5–5 cm/~1–2 in.) and narrow, horizontal gills. The spore print is white. The stalk is cylindrical or slightly thickened at the base with whitish to pink-ochre flesh. Figure 42.1 displays specimens of this mushroom.

Distribution and Ecology: *Clitocybe dealbata* inhabits grasslands in meadow, lawns, pastures, and occasionally near trees, particularly in eastern Canada and the United States.

Common Name: Red-staining Inocybe, Patouillard's Inocybe

Scientific Name: *Inocybe erubescens* A. Blytt (*Inocybe patouillardii* Bres.)

Mycological Family: Cortinariaceae

Physical Description: This moderately large mushroom has a 3–9 cm (~1–4 in.) cap that initially is conical, but as the mushroom ages the cap flattens with involute and then de-curved, irregular, and finally fissured appearance. The cap of young

specimens is white to light ochre, but older specimens have reddish brown to cinnamon-brown caps that have a fibrillose surface. The stem does not contain a bulb and the gills become red with age. The spore print is ochre-brown. Damage and age cause the flesh of the mushroom to turn red, and cutting the mushroom produces a fruity odor.

Distribution and Ecology: *I. erubescens* is found in parks and deciduous forests from late spring to autumn, primarily in May and June.

Common Name: Leaf-loving Clitocybe

Scientific Name: *Clitocybe phyllophila* (Pers.) P. Kumm.

Mycological Family: Tricholomataceae

Physical Description: This moderately large, white mushroom has a convex to flattened cap (5–11 cm/~2–4 in.). The flesh-colored to brown cap has a satin surface with slightly decurrent gills. The spore print is dirty flesh-colored to slightly pink.

Distribution and Ecology: *Clitocybe phyllophila* appears in deciduous forests among leaf litter during the autumn.

Common Name: Lilac or clean Mycena, Amethyst Agaric

Scientific Name: *Mycena pura* (Pers.) P. Kumm.

Mycological Family: Tricholomataceae

Physical Description: This small to moderate-sized mushroom with pink to pink-purple cap (2–6 cm/~1–2 in.) is initially conical and flattens as the mushroom ages. The gills are adenexed with a distinct radish-like smell. The spore print is white.

Distribution and Ecology: *Mycena pura* is a common mushroom found among leaf litter in a variety of diverse habitants including alpine meadows.

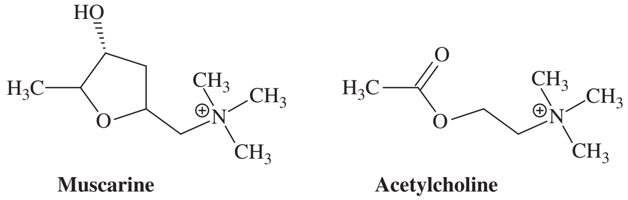

FIGURE 42.2. Chemical structure of muscarine and acetylcholine.

EXPOSURE

In Europe, ingestion of the small white mushrooms of the genera *Inocybe* and *Clitocybe* typically results from the misidentification of small, white mushrooms of famous edible species, such as *Tricholoma terreum* (Schaeff.) Quél., *Clitopilus prunulus* (Scop.) P. Kumm., or *Marasmius oreade* (Bolton) Fr.

PRINCIPAL TOXINS

Physiochemical Properties

L-(+)-Muscarine, which is the quaternary trimethylammonium salt of 2-methyl-3-oxy-5-(aminomethyl) tetrahydrofuran, is the major constituent of toxic mushrooms from the genera *Clitocybe* and *Inocybe*.[5] This compound binds to the acetylcholine muscarinic receptor in the autonomic and postganglionic nerve fibers in the exocrine glands, eyes, bladder, gastrointestinal (GI) tract, lungs, and cardiovascular system. Depolarization results from the binding of muscarine to these receptors. Figure 42.2 demonstrates the structural similarities between muscarine and acetylcholine. Muscarine-containing mushrooms also contain other enantiomers of muscarine (*allo*-muscarine, *epi*-muscarine, *epi-allo*-muscarine). However, these enantiomers are relatively inactive compared with L-(+)-muscarine, and these enantiomers do not contribute to the cholinergic effects of muscarine-containing mushrooms. L-(+)-Muscarine is heat stable, colorless, and water soluble. Prolonged cooking does not reduce the toxicity of muscarine-containing mushrooms.[1]

Poisonous Parts

The muscarine content of *Inocybe* species is highly variable with alkaloid content ranging up to about 0.8% dry weight.[1] *Inocybe nappies* J.E. Lange contains a relatively high concentration (i.e., 0.71% dry weight) of muscarine compared with other North American *Inocybe* and *Clitocybe* species.[6,7]

Mechanism of Toxicity

The activity of L-(+)-muscarine results from the structural similarity of muscarine and acetylcholine. Muscarine stimulates muscarinic autonomic and postganglionic receptors in the central and peripheral nervous systems. The physiological consequence of this action is a variety of GI, cardiovascular, respiratory, genitourinary, and visual effects. Because muscarine does not contain an ester, acetylcholinesterase does not easily degrade muscarine; consequently, the cholinergic activity of muscarine is prolonged compared with acetylcholine.

TOXICOKINETICS

Gastrointestinal absorption of muscarine probably is low based on animal studies.[8]

CLINICAL RESPONSE

Characteristic features of muscarine poisoning include cholinergic effects, such as diaphoresis, salivation, urgency, diarrhea, and blurred vision.[9] Within minutes to 2 hours after ingestion of muscarine-containing mushrooms, muscarinic symptoms begin with GI (nausea, vomiting, diarrhea, abdominal pain) and autonomic (headache, salivation, lacrimation, fasciculations, diaphoresis, miosis, blurred vision) effects. Bronchoconstriction may cause wheezing and dyspnea. Cardiovascular effects primarily involve bradycardia, while the onset of hypotension is rare following the ingestion of muscarine-containing mushrooms. Symptoms are usually mild and resolve within 6 hours. Serious intoxication following ingestion of muscarine-containing mushrooms is rare. The ingestion of a mushroom *Inocybe tristis* Malencon and Bertault by a $2^1/_2$-year-old girl was associated with the rapid onset of diarrhea, vomiting, altered consciousness, and miosis.[10] Subsequently, hypertension and a purpuric rash developed along with transient hepatic, muscular, renal and cutaneous damage. She recovered with supportive care.

DIAGNOSTIC TESTING

Laboratory abnormalities are uncommon following the ingestion of muscarine-containing mushrooms. Case reports suggest that mildly increased serum hepatic aminotransferases may develop after ingestion of some muscarine-containing *Clitocybe* mushrooms.[11]

TREATMENT

Stabilization involves the evaluation of muscarinic effects associated with ingestion of these mushrooms. Serious poisoning is rare because of the low GI bioavailability of muscarine from the mushrooms and the small concentrations of muscarine. Potentially, life-threatening muscarinic symptoms include excessive respiratory secretion, bronchospasm, and cardiovascular collapse. Such patients require monitoring of oxygen saturations, intravenous fluids, cardiac monitoring, and, if indicated, intubation. Atropine is a specific antidote for the drying of bronchial secretions. Decontamination is usually not necessary because of the late presentation (i.e., >1–2 hours).

There are no effective methods to enhance the elimination of muscarine. Atropine antagonizes the effect of muscarine. Starting doses are 0.2 mg for children under 2 years of age, 0.3 mg for children 2–4 years, 0.4 mg for children 4–10 years, 0.5 mg for children 10–14 years, and 0.5 to 1.0 mg for adults depending on the severity of the intoxication. Additional smaller doses may be administered as dictated by the clinical response. Drying of secretions rather than mydriasis is an appropriate endpoint of atropine therapy to avoid atropinization. Patients may be discharged following resolution of muscarinic symptoms, typically in <24 hours.

Chapter 43

ORELLANINE-CONTAINING MUSHROOMS and NEPHROTOXICITY
(*Cortinarius* Species)

HISTORY

The Orellanus syndrome involves the delayed development of renal failure following the ingestion of mushrooms from a group of orellanine-containing fungi, particularly from the genus *Cortinarius* [*C. orellanus* Fr., *C. rubellus* Cooke (*C. orellanoides*)]. Typically, these patients developed gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal cramps, anorexia) within several hours of ingesting these mushrooms followed by renal insufficiency within a few days to weeks after ingestion.[1] Some European and Japanese patients required renal transplantation after developing this syndrome.[2] Orellanus syndrome was first reported in Poland during 1952 following the onset of an epidemic of renal failure in the Konin province.[2] Subsequently, reports from Scotland, France, Switzerland, Finland, and Sweden associated the development of renal dysfunction with the ingestion of *Cortinarius* mushrooms.[4] Although *Cortinarius* species occur in North America, the development of delayed-onset of renal toxicity following the ingestion of mushrooms in North American is rare. However, case reports have associated a similar syndrome of acute gastroenteritis followed by the delayed-onset of nephrotoxicity a few days after the ingestion of mushrooms suspected to be *Amanita smithiana* in the Pacific Northwest of the United States.[5] Other mushrooms implicated in delayed nephrotoxicity include mushrooms from widely separated locations outside the United States, such as unidentified species of *Cortinarius* and *Amanita* in Canada[6] and Australia,[7] *Amanita pseudoporphyria* Hongo in Japan,[8] and *Amanita proxima* Dumée in France.[9] These *Amanita* mushrooms do not contain detectable amounts of orellanine.

MYCOLOGICAL DESCRIPTION

Cortinarius species comprise a large, diverse genus of over 250 species that usually form mycorrhizae with trees in forests. A small number of lemon-yellow *Cortinarius* species are nephrotoxic.[10] The mushrooms from these species have a partial veil composed of fine threads (cortina) connecting the margin of the cap to the stalk, particularly in young specimens. As the mushroom ages, the cortina disappears, resulting in almost indistinguishable remains of the cortina.

Common Name: Poznan Cort Mushroom, Fool's Webcap

Scientific Name: *Cortinarius orellanus* Fr.

Mycological Family: Cortinariaceae

Physical Description: This moderately large mushroom has a yellowish-brown cap (2–8 cm/~1–3 in.) that is conical and covered with fibrils on young specimens. As the mushroom ages, the cap becomes smooth. The spores are elliptical with a rust-brown spore print. The stem is lighter than the cap, manifest by a golden-yellow color.

Distribution and Ecology: Specimens of *C. orellanus* occur in warm deciduous forests near oak and pine trees in continental Europe.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Common Name: Deadly Webcap

Scientific Name: *Cortinarius rubellus* Cooke (*Cortinarius speciosissimus* Kühner & Romagn., *Cortinarius orellanoides* Rob. Henry)

Mycological Family: Cortinariaceae

Physical Description: This moderately large mushroom has a pointed umbo on the rust- to yellow-brown cap (2–12 cm/~1–5 in.) that is conical in shape on young species and more flattened on older specimens. The broad, elliptical spores yield a rust-brown spore print. The cylindrical stalk is similar in color to the cap and the stalk sometimes contains lemon-yellow bands, which represents the remains of the cortina.

Distribution and Ecology: In northern Europe and mountainous areas of central Europe, *C. rubellus* species inhabit moist or wet conifer forests, particularly in moist acidic soil.

EXPOSURE

Nephrotoxic *Cortinarius* species are somewhat morphologically similar to mushrooms from the *Psilocybe* genus, and inexperienced mushroom hunters searching for hallucinogenic mushrooms may misidentify *Cortinarius orellanus* or *Cortinarius rubellus* as *Psilocybe semilanceata* (Fr.) P. Kumm.[11] Misidentification of *C. orellanus* as C*antharellus cibarius* var. *cibarius* Fr. also occurs.

PRINCIPAL TOXINS

Physiochemical Properties

The nephrotoxic mushrooms of the genus *Cortinarius* contain the polar, bipyridyl *N*-oxide compound orellanine [2,2′-bipyridine-3,3′, 4,4′-tetrol (tetrahydroxy)-1,1′ dioxide, CAS RN: 37338-80-0], which is structurally related to paraquat (4,4′-bipyridine) and diquat (2,2-bipyridine).[12] Orellanine is a colorless, blue-fluorescing compound, which decomposes slowly in high heat (150 °C–180 °C/302 °F–356 °F) and UV light to the yellow, nontoxic bipyridyl compound, orelline.[13,14] Decomposition of orellanine is rapid at temperatures over 267 °C (513 °F). However, orellanine is stable for many years in the intact mushroom.[15] Figure 43.1 demonstrates the reduction of orellanine to the nontoxic compound, orelline via the intermediate orellinine. Cooking, freezing, and drying do not reduce the nephrotoxicity of *Cortinarius* species associated with renal damage.[16] *Cortinarius rubellus* contains other cyclic decapeptides (cortinarin A, B) that produce renal damage in animal species,[17] but the role of these decapeptides in causing the Orellanus syndrome remains unclear.[18] Cortinarin C is not associated with nephrotoxicity in animal models. Both orellanine and orelline are practically insoluble in organic solvents and water, but somewhat soluble in methanol and dimethyl sulfoxide (DMSO).[15]

Poisonous Parts

Species associated with the presence of orellanine include *C. orellanus, C. fluorescens* E. Horak, *C. henricii* Reumaux, *C. rainierensis* A.H. Sm. & D.E. Stuntz, and *C. rubellus*.[19] Orellanine content ranged from 0.45% (*C. henricii*) to 1.1–1.4% (*C. orellanus*) as measured by direct electron spin resonance (see Table 43.1).[20] The orellanine content in this study was approximately 2.5–3 times greater in the caps than in the stalks.[21] In dried specimens of *C. orellanus* and *C. rubellus* (*C. orellanoides, C. speciosissimus*), the orellanine content was 14 mg/g and 9 mg/g, respectively.[22]

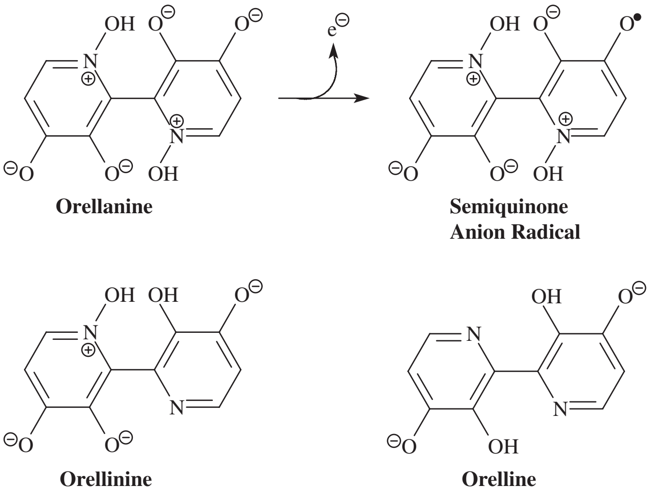

FIGURE 43.1. Chemical structures of orellanine, potential toxic intermediate, orthosemiquinone anion radical, and the reduction products, orelline and orellanine.

TABLE 43.1. Orellanine Content of Selected Cortinarius Species*

Species	Orellanine Content (% Dry Weight)
Cortinarius henricii Reumaux	0.45
Cortinarius orellanus Fr.	1.10
Cortinarius rainierensis A.H. Sm. & D.E. Stuntz	0.85
Cortinarius rubellus Cooke	0.20–0.50

Source: From Ref 20.

*Analytical method direct electron spin resonance with limit of detection = 5 µg.

Mechanism of Toxicity

The mechanism of action of orellanine is not well defined, but the target of orellanine or a toxic metabolite (e.g., orellinine) probably is the renal tubular epithelium.[23,24] Orellanine undergoes photochemical degradation to orellinine, which is reduced to the non-toxic metabolite, orelline. Consumption of nephrotoxic *Cortinarius* species produces a severe interstitial nephritis, acute focal tubular damage, and interstitial fibrosis. Glomeruli are minimally involved. The administration of orellanine produces orthosemiquinone anion and oxygen free radicals that increase oxidative stress by depletion of glutathione and ascorbate as demonstrated in Figure 43.1,[25] but the exact mechanism of toxicity remains unclear.[23] Renal biopsies of patients with renal failure after the ingestion of *Cortinarius* mushrooms demonstrate nonspecific tubulointerstitial changes with marked edema, patchy tubular necrosis, and mild mononuclear inflammatory infiltrates.[26] Immunofluorescence does not demonstrate immune complex deposition in the kidneys. The glomeruli are usually preserved with little if any mesangial reaction, and the renal vessels are patent. Some renal biopsies during the acute phase detected unusual multinucleated tubular giant cells and marked medial muscular hyperplasia of interlobular arteries with no evidence of injury to the intima.[27] Healing occurs via fibrosis with variable amounts of tubular atrophy, patchy tubular loss, and renal dysfunction. During the acute phase, electron microscopy demonstrates mitochondrial swelling, apical cytoplasmic vacuolization, and distorted brush borders in the proximal tubular epithelium.[28] Although a few case reports associate mild hepatocellular damage with *C. orellanus* ingestion,[29] hepatic damage is usually absent in contrast to amatoxin poisoning.[30]

DOSE RESPONSE

Based on case reports, there is considerable variation in the response to orellanine. The degree of renal dysfunction depends on a variety of factors including delay between ingestion and treatment, pre-existing renal disease, internal dose of orellanine, and the general health of the patient.[31] A group of 3 patients sharing a meal of mushrooms from *Cortinarius rubellus* (*C. orellanoides, C. speciosissimus*); 1 patient developed mild gastroenteritis and transitory renal dysfunction, whereas the other 2 patients developed end-stage renal failure that necessitated renal transplantation.[2] The ingestion of 15 *Cortinarius* mushrooms was associated with the development of acute renal failure with slow, partial resolution.[4] A 32-year-old man developed renal failure requiring dialysis after the ingestion of two fruiting bodies from a specimen of *Cortinarius orellanus*.[26] Although his renal function recovered, his serum creatinine remained elevated a month after ingestion of these mushrooms.

TOXICOKINETICS

Orellanine undergoes photoreduction to orellinine, which is subsequently reduced to the nontoxic metabolite, orelline.[32] In a series of 26 patients poisoned by *Cortinarius* mushrooms, the severity of the renal failure did not correlate to acetylation or hydroxylation status of hepatic isoenzyme function.[33] Based on limited testing, the clearance of orellanine from the blood is probably rapid (i.e., <2–3 days).[16]

CLINICAL RESPONSE

The ingestion of nephrotoxic *Cortinarius* mushrooms causes the delayed onset of an acute tubulointerstitial nephropathy that can progress to chronic renal insufficiency. During the initial latent period, some patients develop gastrointestinal symptoms that include nausea, vomiting, and less often abdominal pain, anorexia, and diarrhea. These symptoms are typically mild and begin within the first few days (median: 3 days, range: 12 hours–14 days) after ingestion of *Cortinarius* mushrooms.[34] The gastrointestinal phase of the Orellanus syndrome rarely causes dehydration or electrolyte imbalance. Other symptoms during the prerenal phase include anorexia, headache, chills, burning sensation in the mouth, intense thirst, polydipsia, and polyuria.[29] Fever is not usually part of the clinical presentation. In mild cases, these symptoms resolve over several days without the development of renal dysfunction. In more severe cases, myalgias, intense lumbar pain, flank pain, and oliguria occur over the next 1–2 weeks. Renal failure occurs 4–15 days (median: ~8 days) after ingestion depending on the dose ingested.[34] Diuresis typically begins about 7–10 days after the development of acute renal failure. Mortality is low following the use of hemodialysis. A substantial number of cases develop permanent renal dysfunction, but the actual number of patients with chronic renal failure after orellanine poisoning varies between different series of orellanine intoxication. In a study of 26 patients with nephrotoxicity secondary to *Cortinarius* mushroom ingestion, the incidence of end-stage renal failure requiring dialysis and renal transplantation was approximately 8%,[33] whereas 9 (41%) of 22 Swedish patients developed end-stage renal disease after ingesting mushrooms from *Cortinarius rubellus* (*C. orellanoides, C. speciosissimus*).[35] Anorexia and malaise may persist for months.

DIAGNOSTIC TESTING

Rapid analytical procedures are available to detect orellanine via thin layer chromatography (TLC) on silicagel or cellulose plates after extraction of the mushroom or tissue up to at least 60 days after ingestion.[36,37] Other analytical methods include electrophoresis on agarose gel (limit of detection [LOD] = 25 ng), direct electron spin resonance (LOD = 5 µg), and high performance liquid chromatography (HPLC; LOD = 50 pg).[20,38] In a woman who developed interstitial nephritis after the ingestion of mushrooms from *Cortinarius orellanus*, the orellanine concentration was 6.12 mg/L in a plasma sample drawn 10 days after ingestion as measured by direct spectrofluorometry on two-dimensional thin-layer chromatograms after specific photodecomposition to orelline.[39] The orellanine concentration in the first renal biopsy obtained 13 days after ingestion was 7 µg per 25 mm^3. The second renal biopsy taken 6 months later demonstrated 24 µg per 8 mm^3.

Laboratory abnormalities include leukocyturia, hematuria, and proteinuria along with elevation of the serum creatinine and serum potassium. Depending on the severity of the renal failure, hyperphosphatemia, hypocalcemia, and metabolic acidosis may also occur.

TREATMENT

The mainstay of treatment is supportive care with careful management of fluid and electrolyte balance as well as the use of hemodialysis as needed. Prolonged monitoring of renal function is necessary because of the slow resolution of kidney dysfunction. *In vitro* studies suggest that hemoperfusion materials adsorb orellanine, particularly activated charcoal.[40] However, there are inadequate clinical and toxicokinetic data, especially during the first 24 hours after ingestion, to confirm or exclude the efficacy of hemoperfusion or hemodialysis. Experimental studies in rats suggest that nephrotoxicity begins within 40 hours of ingestion,[41] and in animal studies the kidneys excrete detectable quantities of orellanine only for the first 24 hours after exposure.[42] Hemodialysis and hemoperfusion probably do not remove clinically significant amounts of orellanine more than 1–2 weeks after ingestion, and during the subsequent period the use of hemodialysis depends only on the need to support renal function. There are no antidotes.

Outcome depends on a variety of factors including delay until supportive therapy, pre-existing renal disease, internal dose of orellanine, and the general health of the patient.[31] Recovery of renal function is slow, and therefore renal transplantation usually occurs over 10 months after ingestion.[34] Case reports associate the use of corticosteroids and *N*-acetylcysteine with clinical improvement,[43] but the variable course of renal dysfunction after orellanine poisoning and the lack of clinical data limits conclusions about the efficacy of these treatment modalities.

Chapter 44

PAXILLUS and OTHER MUSHROOM SYNDROMES

HISTORY

The Paxillus syndrome is a food allergy manifest by hemolytic anemia and renal failure. This idiosyncratic reaction was reported in Germany during the early 1960s after the development of this syndrome following ingestion of mushrooms previously considered edible.[1] Studies during the early 1970s indicated that the hemolysis associated with this syndrome resulted from an immune-mediated rather than a toxic reaction.[2]

MYCOLOGICAL DESCRIPTION

Common Name: Brown Roll-Rim, Common or Poisonous Paxillus, Brown Chanterelle

Scientific Name: *Paxillus involutus* (Batsch) Fr.

Mycological Family: Paxillaceae

Physical Description: This moderately large, ochre to red-brown ochre mushroom has a large cap (5–25 cm/~2–10 in.) with a margin that curves inward. The decurrent gills have a whitish to light ochre color that becomes olive-yellow to ochre-brown with aging. The spore mass is ochre-brown to rust. The sour-smelling, white to pale ochre flesh easily turns reddish-ochre after trauma.[3]

Distribution and Ecology: *Paxillus involutus* is a common mushroom in conifer and deciduous forests, particularly in damp areas including roadsides, parks, and gardens during late summer to late fall.

Common Name: Yellow Tricholoma, Man-on-Horseback, Chevalier

Scientific Name: *Tricholoma flavovirens* (Fries) Lundell (*Tricholoma equestre*)

Mycological Family: Tricholomataceae

Physical Description: *Tricholoma flavovirens* has a yellow to yellowish-brown, viscid cap, yellow notched gills, a robust stature, and pale yellow stipe. Fleshy stalk with sinuate to notched gills, and a white spore deposit.

Distribution and Ecology: This mushroom appears from late fall through mid-winter in sandy soils in conifer forests.

Common Name: Smith's Amanita, Smith's Lepidella

Scientific Name: *Amanita smithiana* Bas

Mycological Family: Amanitaceae

Physical Description: An unpleasant smelling white mushroom that stains light cinnamon to yellow-brown with age or bruising. The gills and spores are white, and the stem contains a ring. The cap has warts that may disappear in rain or hot, dry weather.

Distribution and Ecology: *Amanita smithiana* inhabits the Pacific northwestern United States and southwestern British Columbia. This fungal species prefers areas of moss under conifers in these regions.

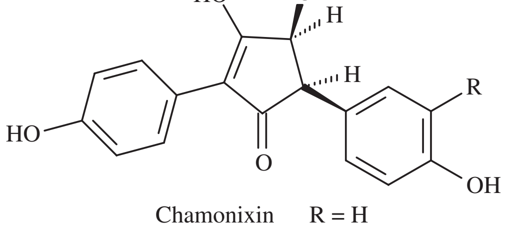
EXPOSURE

Matsutake (pine mushroom) is a common name applied to edible species from the genus *Tricholoma*. The American matsutake [*Tricholoma magnivelare* (Peck) Redhead], which grows primarily in the Pacific Northwest, is a relative of the Japanese matsutake [*Tricholoma matsutake* (S. Ito & S. Imai) Singer]. The mistaken identification of *Amanita smithiana* as a pine mushroom can result in poisoning, although the odor of this latter mushroom is not as spicy as matsutake mushrooms.

PRINCIPAL TOXINS

Paxillus Syndrome

The active constituent or antigen for the Paxillus syndrome has not been identified. *Paxillus involutus* contains a phenol, involutin, which oxidizes to a brown compound that accounts for the brown discoloration following damage of fresh specimens.[4] Figure 44.1 displays the chemical structure of involutin and the closely related compound, chamonixin. During an animal study, test animals received 50 or 250 mg/kg body weight of an aqueous suspension composed of dried homogenized mushrooms from *Paxillus involutus* collected near the Arctic Circle in Finland.[5] There were no observable differences between control and test rats. Experimental observations included general behavior, body weight, gross and microscopic changes in major organs, and the relative weights of the liver, kidney, and heart. Examinations of Polish mushroom specimens indicate that *Paxillus involutus* does not accumulate heavy metals, such as mercury.[6] *In vitro* studies indicate that the active fraction is a nonpolar, acid- and thermo-stable cytotoxic principle.[7] Some specimens of *Paxillus involutus* produce gastroenteritis when eaten in one geographical area, but in other locations this mushroom is edible when properly prepared. The onset of the Paxillus syndrome results from the ingestion of the *Paxillus involutus* mushroom by sensitized patients. The presence of an immune-complex directed at erythrocytes causes hemolytic anemia with subsequent renal damage. Attachment of immune complexes to the erythrocytes results in activation of complement, lysis of the red blood cells, and hypotension. Inadequate renal perfusion increases renal damage.



Chamonixin R = H
Involutin R = OH

FIGURE 44.1. Chemical structures of involutin and chamonixin.

Myotoxins

Animal studies suggest that the myotoxic effects of *Tricholoma flavovirens* (Pers.) S. Lundell results from a nonspecific response to large ingestions by sensitive individuals. The administration of dried extract from these mushrooms produces diarrhea, tachypnea, reduced motor activity, and histological changes in the muscle fibers of mice.[8] Similar reactions occur in rodent studies with other presumably edible species including *Russula subnigricans* Hongo, *Cantharellus cibarius* Fr. var. *cibarious* (chanterelle), *Leccinum versipelle* (Fr. & Hök) Snell (brown birch boletus), and *Albatrellus ovinus* (Schaeff.) Kotl. & Pouzar (sheep polypore).[9] The toxins in *T. flavovirens* and *Russula subnigricans* have not been identified. The latter mushroom species contains cytotoxic triphenyl ethers, russuphelins A–F.[10,11]

Renal Toxins

The renal toxins present in *Amanita smithiana* are not well defined. Mushrooms from *Amanita smithiana* and *Amanita pseudoporphyria* Hongo species contain a suspected nephrotoxin, but no detectable amounts of amatoxins are present in these mushrooms. Partial isolation of the renal toxin from *A. smithiana* indicates that this renal toxin has different physical properties (e.g., UV light stability, shorter latency period) than orellanine.[12] In contrast to most other *Amanita* species, specimens from *A. smithiana* contain 2(S)-amino-4,5-hexadienoic acid and trans-2-amino-5-chloro-4-hexenoic acid, but these compounds are not definitely nephrotoxic in animal models.[13] The role of allenic norleucine as a nephrotoxin also is unclear.

Acromelalgia

Analysis of specimens from *Clitocybe amoenolens* demonstrate neuro-excitatory amino acids (acromelic acids), primarily acromelic acid A–E. These compounds are structurally similar to nonprotein pyrrolidine dicarboxylic acids including kainic acid and domoic acid as demonstrated in Figure 44.2. In rodent studies, acromelic acid A is the most potent glutamate agonist, but a direct causal link between acromelic acids and acromelalgia has not been established. Analysis of dried specimens

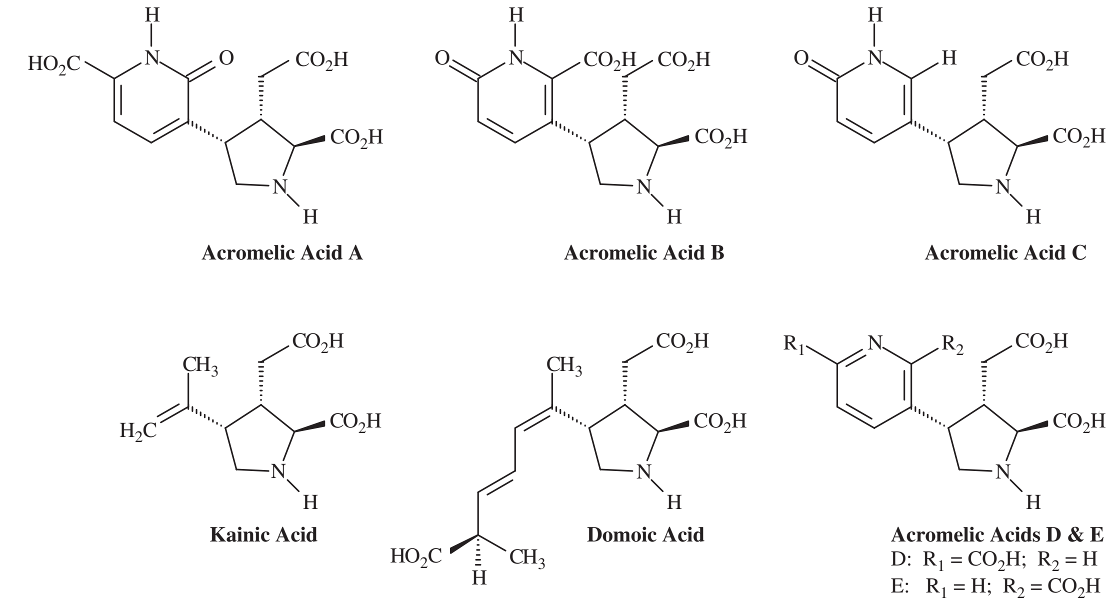


FIGURE 44.2. Chemical structures of acromelic acids A-E, kainic acid, and domoic acid.

of *C. amoenolens* and *C. acromelalga* detected acromelic acid A concentrations of 325 ng/mg and 283 ng/mg, respectively, as measured by liquid chromatography/mass spectrometry (LC/MS).[14] The limit of quantitation for this method was 10 ng/mg.

CLINICAL RESPONSE

Rare case reports associate anaphylaxis (angioedema, dyspnea) with the ingestion of the Japanese matsutake mushrooms [e.g., *Tricholoma matsutake* (S. Ito & S. Imai) Singer] by atopic individuals.[15]

Gastroenteritis

The ingestion of inadequately prepared *Paxillus involutus* mushrooms can produce the acute onset of gastroenteritis that is self-limited.[3] This toxic reaction should not be confused with the Paxillus syndrome, which occurs *only* in sensitized patients. This immune reaction commonly occurs in patients with a history of adverse reactions following the consumption of *Paxillus involutus* mushrooms. Initial symptoms include nausea, vomiting, diarrhea, and abdominal cramps followed by the development of the clinical features of hemolytic anemia and renal failure.

Rhabdomyolysis

Case reports have associated the ingestion of *Tricholoma equestre* (*T. flavovirens*) mushrooms with the delayed onset of muscle weakness and rhabdomyolysis.[16] These patients developed fatigue, muscle weakness, and myalgias 1–3 days after eating at least three consecutive meals of this mushroom.[8] The symptoms worsened over the next several days with the onset of facial erythema, nausea, diaphoresis, and dark urine. Three patients developed hyperthermia and died from multiple organ failure. Severe rhabdomyolysis (serum creatine phosphokinase >100,000 IU/L) and refractory heart failure preceded death in these patients. Some of these patients developed substantial elevation of serum hepatic aminotransferases, but there was no hepatorenal failure except in the patients with multiple organ failure *and* hyperthermia. The symptoms in survivors resolved without complications over several weeks.[17] A case report associated the development of coma, acute respiratory failure, convulsions, and generalized muscle weakness without significant elevation of serum creatine kinase in a pediatric patient following the ingestion of 300–400 g *Tricholoma equestre* (*T. flavovirens*) daily for 4 consecutive days.[16] Symptoms resolved over 12 days with supportive care including respiratory support that required intubation. These myotoxic reactions may be idiopathic because a case series did not detect rhabdomyolysis in adults ingesting similar doses of *Tricholoma equestre*. A study of 13 healthy volunteers did not demonstrate any significant elevations of serum creatine phosphokinase or serum hepatic aminotransferases following the ingestion of up to 1200 g *Tricholoma equestre* daily for 4 days.[18] Severe rhabdomyolysis with hyperkalemia, respiratory insufficiency, acute renal failure, and shock has been associated with the ingestion of *Russula subnigricans* Hongo in Japan.[19]

Renal Toxicity

Several case series associate the ingestion of mushrooms with the development of acute tubulointerstitial nephropathy and renal dysfunction 1–4 days after ingestion of mushrooms suspected to be *A. smithiana* Bas from the Pacific Northwest of the United States[20–22] and *Amanita proxima* Dumée from southern France.[23] The onset of gastrointestinal (GI) symptoms and renal dysfunction in these patients was more rapid than the renal failure associated with *Cortinarius orellanus*. Following consumption of these *Amanita* species, GI distress (nausea, vomiting, diarrhea, abdominal cramps, anorexia), malaise, diaphoresis, lightheadedness, and renal dysfunction developed within 12 hours of ingestion, in contrast to the delayed onset renal insufficiency associated with orellanine nephrotoxicity. Although the mushrooms reportedly were *Amanita smithiana* in the Pacific Northwest cases, no definitive identification of the actual mushrooms involved with these cases was made. Gastrointestinal symptoms typically began about 5–6 hours after ingestion and persisted for several days before renal failure developed. In a few case reports, the GI symptoms developed within 1–2 hours of the ingestion of the mushrooms, primarily following the ingestion of raw mushrooms.[20] There was moderate elevation of serum hepatic aminotransferases in some patients, but no significant hepatic dysfunction occurred and all patients recovered after at least several weeks with supportive care and hemodialysis as required.

Acromelalgia (Erythromelalgia)

A French case series of 7 patients associated the consumption of *Clitocybe amoenolens* Malencon with the development of distal paresthesias and intense, paroxysmal dysesthesias.[24] Symptoms developed >24 hours after ingestion of the mushrooms, particularly in the feet at night. Although there were no prominent skin lesions, a sensation of local heat, local erythema and edema occasionally occurred. Hepatorenal dysfunction and GI distress did not develop. Heat and pressure exacerbated the paresthesias, while immersion of the affected extremities in cold water provided some relief. Symptoms resolved in 1–4 months. Similar cases of erythromelalgia following the ingestion of *Clitocybe acromelalga* Ichimura have been reported in Japan since the end of the 19th century.

DIAGNOSTIC TESTING

Laboratory findings following the development of the Paxillus syndrome include evidence of hemolysis (increased serum haptoglobin, hemoglobinuria, anemia) and renal failure (elevated serum creatinine, electrolyte imbalance). Case reports indicate that specific IgG antibodies against membrane particles of *Paxillus involutus* are present in the serum of patients with the Paxillus syndrome as measured by serum hemagglutination tests.[25] Blood type potentially can alter the hemaglutination of human red blood cells by these IgG antibodies.[26] Patients, who ingest several meals of *Tricholoma equestre* (*T. falvovirens*) mushrooms, may develop rhabdomyolysis, but electrolytes and serum creatinine usually remain normal.[27] Electromyograms in these patients demonstrated isolated muscle damage with preservation of sensorimotor function. Some elevation of serum hepatic transaminases may occur in these patients, but hepatorenal failure usually does not occur unless the patient develops multiple organ failure.

TREATMENT

Treatment is supportive. Patients should be evaluated for hypotension secondary to anemia and renal dysfunction. Blood transfusions and hemodialysis may be necessary depending on the severity of the hemolytic anemia and renal dysfunction associated with the Paxillus syndrome. There are few data to guide management. A case report documented the reduction of free hemoglobin and immune complex levels by 60–75% following the use of plasma exchange with 3,000 mL albumin.[25] However, the patient required hemodialysis for the treatment of acute renal failure and the effectiveness of plasmapheresis in reducing renal damage or hemolysis remains undetermined. Patients ingesting multiple meals of *Tricholoma equestre* should be evaluated for rhabdomyolysis (serum creatine phosphokinase, urine myoglobin) as well as the development of multiple organ failure in symptomatic patients. Patients with rhabdomyolysis should receive generous fluid replacement to ensure adequate urine output (1–2 cc/kg/h) and alkalinization for the treatment of metabolic acidosis to prevent the excretion of highly acidic urine as needed.

Treatment of ingestions of mushrooms from *Amanita smithiana* is supportive including correction of fluid and electrolyte imbalance. These patients should be monitored for the development of renal failure within the first 2–4 days after ingestion. There are no antidotes. Renal function usually returns to baseline values after supportive care and hemodialysis as needed.

II Mycotoxins

Chapter 45

MYCOTOXINS

HISTORY

Historical literature documents the toxic effects of fungi since ancient times. In the 7th and 8th centuries BC, the festival of Robigalia honored the god Robigus, who protected the grain and trees during the spring when the crops were susceptible to attack by rust and mildew.[1] The Old Testament (Leviticus 14:37–45) contains passages concerning the presence of greenish or reddish streaks of mildew on the walls of houses that required removal. The first documented mycotoxicosis occurred in the Middle Ages during the epidemics of hallucinations, delirium, convulsions, and gangrene known as St. Anthony's Fire. By the l850s, this disease was called ergotism, and the fungus, *Claviceps purpurea* var. purpurea (Fr.) Tul. was the recognized etiological agent.[2] In 1948, Freeman et al isolated the first trichothecene mycotoxin from the mold *Trichothecium roseum* (Pers.) Link.[3] The trichothecene mycotoxin, T-2 toxin, was a *suspected* etiological agent for numerous alimentary toxic aleukia (ATA)- related fatalities that occurred in Russia during the latter part of World War II.[4] Interest in mycotoxicoses increased after the isolation of a mycotoxin called aflatoxin from the mold *Aspergillus flavus* Link in Ugandan peanuts during the late 1950s.[5] Consumption of these contaminated peanuts by turkeys and ducks (Turkey X disease) caused hundreds of thousands of deaths in animals during the early 1960s. Subsequently, aflatoxin B_1 was identified as a potent natural carcinogen.[6,7] The World Health Organization cited three other classes of mycotoxins (ochratoxin, zearalenone, trichothecenes) as potential animal and human health hazards. In 1965, ochratoxin A was the first toxin isolated from *Aspergillus alutaceus* Berk. & M.A. Curtis.[8] In the last several decades, major outbreaks of human mycotoxicoses included hepatitis from the consumption of aflatoxin-contaminated maize in Kenya and India,[9] gastroenteritides from the consumption of ergot-contaminated pearl millet in India, a self-limited gastroenteritis from the ingestion of deoxynivalenol in bread made from moldy Indian wheat,[10] and a diarrheal disease associated with the consumption of fumonisin B_1-contaminated sorghum and maize.[11]

CLASSIFICATION AND IDENTIFICATION

The kingdom of fungi includes mushrooms, toadstools, puffballs, truffles, molds, mildew, smut, rusts, and yeast. Because fungi lack chlorophyll, these organisms must absorb food from outside their bodies by releasing digestive enzymes. Fungi account for about 25% of the biomass of the earth, and the decomposition of organic material by these ubiquitous organisms is an essential part of the energy cycle.[12] The taxonomical classification of fungi divides fungi into five main phyla: Ascomycota (e.g., yeasts, powdery mildews, the black and blue-green molds), Basidiomycota (e.g., most mushrooms, smut/rust in plants, bracket fungi, and puffballs), Chytridomycota (water molds), Glomeromycota (blastospore-producing fungi), and Zygomycota (e.g., black bread mold and other molds including *Mucor, Rhizopus*). Fungi may be unicellular or multicellular. Multicellular fungi are composed of microscopic, branched, interwoven filaments

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

called hyphae that form a visible mass called the mycelium. Yeasts are unicellular fungi that do not produce a mycelium, and these organisms reproduce by budding rather than spores. Most yeast form round, pasty, or mucoid colonies rather than the fluffy colonies formed by the mycelium of multicellular fungi. Mold and mildew are not scientific terms because these terms are applied to visible fungal colonies that may belong to any one of the five fungal phyla. Mold commonly refers to visible fungal growth, and mildew frequently refers to fungal growth on household materials or plants. Fungi are ubiquitous both in indoor and outdoor air.

Properties

These filamentous organisms absorb nutrients by the digestion of food sources in the environment. Fungi are eukaryotic organisms that lack chlorophyll. The cell walls of these organisms primarily contain chitin (acetylglucosamine polymers) along with smaller concentrations of β-(1,3)-D-glucans, mucopolysaccharides, and polysaccharides. Fungi produce a variety of volatile organic compounds including alkanes, aldehydes, esters, ethers, alcohols, ketones, terpenes, terpene derivatives, and sulfur compounds (e.g., dimethyl disulfide).[13] These volatile compounds account for the musty smell associated with mold growth.

Mycotoxins are relatively nonvolatile, low-molecular-weight, secondary toxic metabolites of certain microscopic fungi (molds) that occur primarily on food as a result of fungal growth. At normal ambient temperatures, these complex molecules are usually nonvolatile.[14] These mycotoxins have no apparent physiologic function, but these compounds potentially increase food sources for the mycotoxin-producing fungi by decreasing competition for these food sources. The ingestion of these toxins by higher vertebrates produces toxic reactions known as mycotoxicoses. Mass outbreaks of mycotoxicoses are much more common in domestic animals than in humans, particularly during periods of food scarcity. Although allergic reactions to airborne molds are common, occurrences of mycotoxicoses following inhalation are not well documented. The appearance of mycotoxins result primarily from the growth of three genera (*Aspergillus, Fusarium, Penicillium*), and these toxic metabolites usually appear in the human food chain after replication of these fungi ceases.[15] Although species of *Cladosporium* contain biologically active metabolites (cladosporin, isocladosporin, cladospolides A and B, calphostins),[16] these compounds have not been associated with human or animal toxicity.[17] In contrast to mycotoxicoses, mycoses (e.g., blastomycosis, histoplasmosis, coccidioidomycosis) are infectious diseases, which require fungal replication in the host prior to the development of the disease. Mycotoxicoses are more common in developing countries than in developed countries because of the occurrence of food shortages, improper cultivation and storage methods, and poor cooking techniques. Well-known mycotoxins with medicinal benefits include the antimicrobial agents, penicillin (*P. chrysogenum* var. *chrysogenum* Thom), cephalosporins, and griseofulvin as well as immunosuppressive drugs (cyclosporin) and cholesterol-lowering medications (lovastatin).

Occurrence

Fungi are ubiquitous because of their ability to grow on almost any substrate. There are an estimated 100,000 species of fungi, which represents about one-half of the total species on the earth. Mycotoxins are nonvolatile, secondary metabolites of fungi that are not involved in any physiologic process within the fungus, and the mycotoxins occur in all parts of the fungal colony. Mycotoxins do not penetrate intact human skin, and inhalation of these molecules requires the generation of an aerosol of substrate, fungal elements, or spores. Mycotoxins do not represent a single class of chemical compounds because of their diverse chemical structures (e.g., polyketides, terpenes, indoles). These low-molecular-weight compounds range from single heterocyclic ring with a molecular weight of 50 Da to irregularly arranged 6–8 member rings with molecular weights exceeding 500 Da. Most mycotoxin-producing fungi belong to the class Ascomycetes in the phylum Ascomycota.

Food

Due to the widespread occurrence of fungi, the potential for ingesting mycotoxin-contaminated food is considerable when growing conditions are favorable. Most clinical syndromes associated with the mycotoxins involve the ingestion of contaminated food.[18] The most common fungal genera associated with mycotoxin production in food are *Aspergillus, Fusarium*, and *Penicillium*.[19] In a study of 84 cured fish samples collected in Nigeria, the most common fungi species were *Aspergillus niger* var. *niger* Tiegh. and *Aspergillus flavus* followed by *A. chevalieri* Thom & Church, *A. fumigatus, Penicillium* spp. including *P. citrinum* Thom, *Cladosporium herbarum* (pers.) Link, and *Basipetospora* species.[20,21] *Fusarium* species are destructive pathogens in cereal crops that produce mycotoxins before or shortly after harvest. Mycotoxin-producing species of *Aspergillus* and *Penicillium* may be pathogens or commensals, but mycotoxin production usually occurs during storage rather than crop production. Table 45.1 lists known mycotoxins potentially present

TABLE 45.1. Potential Mycotoxins in Human Foods and Animal Feed

Commodity	Situation	Mycotoxins
Cereals	Preharvest fungal infection	Deoxynivalenol, T-2 toxin, nivalenol, zearalenone, alternariol, alternariol monomethyl ether, tenuazonic acid fumonisins
Maize, peanuts	Preharvest fungal infection	Aflatoxins
Maize, sorghum	Preharvest fungal infection	Fumonisins
Stored cereals, nuts, spices	Damp, inadequate storage conditions	Aflatoxins, ochratoxin
Fruit juice	Fruit mold	Patulin
Dairy products	Animal consumption of mold-contaminated feeds	Aflatoxin M_1, cyclopiazonic acid, ochratoxin, compactin, cyclopaldic acid
Meat and eggs	Animal consumption of mold-contaminated feeds	Patulin, citrinin, ochratoxin, cyclopiazonic acid, cyclopaldic acid, citromycetin, roquefortine, fumonisins
Oilseeds	Preharvest fungal infection	Tenuazonic acid, alternariol

in foods and animal feed, including organically grown commodities.[22]

Table 45.2 lists the toxins associated with mycotoxin-producing fungi. *Trichoderma* species are infrequent producers of mycotoxins.[23]

Cultivation techniques, storage practices, and favorable weather conditions (e.g., >15% moisture content, 90–95% relative humidity, temperature range –8 °C–35 °C/18 °F–95 °F) at both harvest and storage time strongly influence the production of mycotoxins. Other factors affecting mycotoxin concentration include microbial genetics, minimum climatic conditions (moisture content, temperature), substrate, variations within species, the presence of other fungal species,[25] and the geographic distribution of mycotoxin-producing fungi.[5,26] The presence of mycoviruses also may affect the formation of mycotoxin by either inducing or reducing mycotoxin production through mechanical damage and alteration of mycotoxin metabolism.[27] Mycotoxins contaminate commercial and homemade food sources, particularly in Africa. In a survey of Tunisian patients who displayed symptoms compatible with mycotoxicoses, aflatoxins were detected in homemade and commercial food products; ochratoxin A and citrinin were found preferentially in homemade food sources.[28] Mycotoxin-induced diseases usually result from the ingestion of contaminated food sources.

Ambient Air

In well-constructed homes without water contamination, the indoor concentration of fungi generally reflects the outdoor concentration of fungi, typically in the range of 40–80% of the outdoor fungal concentration.[29] Although the presence of mold, moldy odors, and water damage usually indicates the presence of high concen-

trations of indoor fungi, epidemiological studies have not demonstrated a direct correlation between the subjective evaluation of respiratory complaints (e.g., questionnaires) and objective measures of fungal growth, in part because of systemic reporting bias.[30,31] In a prospective study of respiratory allergens and neonatal asthma, the characteristics of the home were not statistically correlated to the viable fungal count (propagules).[32] The questionnaire included design and age of house, ventilation (heating, air conditioning, humidifiers), flooring, observation of moisture problems (house dampness, flooding, mold growth), household occupants, pets, pests, cleaning techniques, and household income/educational level. There are limited data on the clinical relevance of the results from these sampling techniques to long-term health effects. Molds are indoor allergens, but other indoor and outdoor allergens are more important causes of hypersensitivity reactions than molds. In a study of the prevalence of allergic rhinitis and asthma in 395 members of a rural Israeli community, the most common genera of mold were *Aspergillus*, *Penicillium*, *Alternaria*, and *Cladosporium*.[33] Most of the subjects with allergies to molds in this study did not have significant respiratory complaints despite being allergic to molds present in the ambient air of their homes, and the abundance of molds did not correlate to the severity of respiratory symptoms. In general, the production of significant amounts of mycotoxins requires water activity (a_w) levels at the surface of the construction material exceeding 0.95. The mycotoxin content of spores of common indoor fungi (e.g., *Aspergillus, Penicillium*) is usually relatively low.[34] The exception is *Aspergillus versicolor* (Vuill.) Tirab., which can contain up to 1% sterigmatocystins wet weight, when the water activity is close to one. Bulk sampling helps confirm the potential severity of mold exposure, but chemical analyses are necessary to verify the presence of mycotoxins in mycotoxin-forming species.[35] Furthermore, exposure to indoor mold occurs primarily via inhalation of spores, and the presence of fungal species in bulk samples does not correlate to airborne concentrations of fungal spores.

Identification of Fungal Genera and Species

Molds are natural constituents of indoor and outdoor air, and most commercial and residential structures contain low concentrations of fungi on household surfaces and in ambient air. Mold-free environments do not occur naturally without interventions to produce a sterile environment. For example, there are about 20,000–25,000 species in the class Basidiomycetes (mushroom, puffballs, bracket fungi), and separation of the spores from individual species within the class Basidiomycetes is difficult because of the structural similarity of the spores. Species from the classes Ascomycetes and Basidiomycetes produce prolific numbers of spores that account for a majority of spores in the air.[36] Ascospores and basidiospores are associated with very humid conditions (e.g., fog, warm rain). After rain, the ascospore count rapidly decreases, but the basidiospore count usually remains elevated for 2–5 days.[37] During the 3–4 days after a rain, *Cladosporium* and, to a lesser extent, *Alternaria* spore counts also increase. In addition, *Alternaria* counts increase during hot, dry winds from the desert (e.g., Santa Ana winds of Southern California).

The concentrations of spores in ambient air depend primarily on outdoor mold concentrations and indoor humidity as well as time of day, season, climate, building materials, indoor temperatures, ventilation, indoor materials (furniture, carpeting), and the presence of plants. Indoor spore counts in commercial, urban buildings are usually less than residential buildings as a result of differences in cleaning schedules, natural ventilation, and the presence of pets.[38] Air sampling of home environments demonstrates the presence of a wide variety of filamentous fungal genera and species as well as gram-positive bacteria (*Micrococcus* spp., *Staphylococcus* spp., *Streptococcus* spp.), gram-negative bacteria (*Pseudomonas* spp., *Aeromonas* spp.), endospore-forming bacilli (*Bacillus* spp.), and yeasts.[39] In a prospective study of over 1000 houses in the Northeastern United States, air samples of fungal airborne propagules demonstrated 44 fungal genera and 116 fungal species.[32]

The specific concentration and type of fungi present in air samples depends on a variety of factors including the season, time of day, weather conditions (humidity, temperature, wind, snow), location, local flora and fauna, adjacent landscape near buildings, type of ventilation, wall-to-wall carpeting, the presence of pets or water leaks, and the analytical method.[40,41] The most common fungal genera in indoor air samples include *Alternaria, Aspergillus, Aureobasidium, Cladosporium*, and *Penicillium* depending primarily on humidity, season, and temperature.[42–44] Other factors that promote the growth of indoor fungi include wet plant containers (e.g., wicker), pets, absence of cleaning activities (wiping, dusting, vacuuming) or ventilation, and wet organic material (vegetable peels, jute-backed carpeting). The drying of wet organic materials within 3 days usually prevents the development of excessive mold growth, but the persistence of wet materials beyond this period encourages mold growth, particularly when the moist conditions exist longer than 2 weeks.[37] Some species of *Penicillium* and *Aspergillus* grow and reproduce effectively indoors without an outdoor source or an indoor water source. Most strains of *Penicillium* and *Aspergillus* species

present in indoor air samples produce either no or low concentrations (i.e., few ng/g material) of mycotoxins.[34,45] Individual species of a specific fungal genus may vary substantially in samples from indoor and outdoor air.[46] *Cladosporium* was the most frequent genus of fungi in indoor ambient air samples from coastal sections of California, whereas *Alternaria* was more common in samples from the dry sections of interior California.[47] In another study of spore counts in coastal Southern California homes, the common spores in descending order of frequency were *Cladosporium*, basidiospores, *Alternaria*, smut, and ascospores.[37] The most common outdoor fungal species are *Cladosporium* and *Alternaria* as well as *Aspergillus*, and *Penicillium. Cladosporium* and *Alternaria* species grow on the surfaces of plant leaves, whereas *Penicillium* and *Aspergillus* species easily grow on topsoil and decaying litter. The concentration of total fungi colonies in indoor and outdoor air samples is usually lowest in winter, increases in spring, maximizes in summer, and declines in the fall.[42] In general, total fungal counts are highest indoors during the fall and winter, whereas the highest numbers of spores outdoors typically occur in the summer. The concentrations of *Cladosporium* and *Alternaria* are usually higher in samples from outdoor air than indoor air, whereas the concentrations of *Aspergillus* and *Penicillium* are usually higher in indoor air samples than in outdoor air samples.[30] The concentration of an individual fungal genus can vary substantially with seasons. In one location, the outdoor concentration of *Cladosporium* ranged from 26 CFU/m^3 in the winter to >11,000 CFU/m^3 in the summer.[48] Within a given locality the variation in the indoor fungi concentrations is greater in samples from the same house during different time periods than in air samples from nearby houses.[49,50]

Fungal Spore Concentrations

Current cross-sectional air sampling techniques from indoor and outdoor ambient air samples include culturable fungal spores (i.e., colony-forming units/m^3 or CFUs) and total (nonculturable) fungal propagule counts (nonviable and viable spores). Because outdoor air is the dominate source of mold, indoor air samples of fungi are qualitatively similar to outdoor air samples with the ratio of indoor to outdoor concentrations of specific fungal genera typically being <0.5–1 in air samples from buildings without heavy fungal growth.[51] Outdoor spores infiltrate buildings through openings (e.g., air intakes, windows, cracks). The concentrations of fungi in indoor and outdoor air samples typically are similar, except when outdoor air samples contain few fungi during periods of snow. Comparing indoor and outdoor air samples of fungi requires consideration of many factors including sampling techniques, weather, season, geographic region, and timing of the sample. Although molds grow during the whole year, cool temperatures during winter decrease total spore counts substantially. The highest mold counts in outdoor air samples usually occur during the summer and autumn when substantial accumulation of dead organic debris occurs.[30] Most indoor environments contain some fungi, and the assessment of indoor fungal concentrations should include comparable numbers of indoor and proximate outdoor air samples when comparing indoor and outdoor fungal concentrations.[29] Ideally, air sampling should include one or more control houses without complaints in the nearby community. Accurate comparisons of indoor and outdoor fungal samples require identification of fungal species rather than fungal genera. The presence of high concentration of fungi species in indoor air samples indicates the presence of excessive indoor moisture, but the lack of well-documented dose-response data for the development of clinical symptoms limits conclusions regarding the concentrations of fungi that cause adverse health effects. Spores remain airborne for various lengths of time, depending on the settling velocity, but these spores eventually settle on interior surfaces. Reservoirs for spores include carpeting, ducts, and filters for heating and air conditioning systems. Mechanical agitation of local surfaces (e.g., scraping, touching, vibration, air flow) and human activity (walking, sitting, moving household items) generate significant airborne release of spores to the ambient air.[52] In particular, the drying of spores (e.g., *Stachybotrys*) that normally reside in a sticky medium substantially increases the airborne count of these spores.

Colony-Forming Units. The culturable spore sampling technique (e.g., Anderson sampler) involves impaction of culturable organisms onto nutrient agar or impingement of the spores on transport media for later transfer to culture media as measured in CFU/m^3. The primary advantage of the culture techniques is the ability to identify *potentially* toxic fungal species. However, the use of different culture media and variation in growth rates among fungal species may result in the underestimation of the fungi based on viable counts alone, particularly when the fungal concentrations are low and the sample size is small. In a study of >12,000 fungal air samples collected during indoor air quality investigations in the United States between 1995 and 1998, the median indoor and outdoor fungal counts were 82 CFU/m^3 (95th percentile = 1,200 CFU/m^3) and 540 CFU/m^3 (95th percentile = 3,200 CFU/m^3), respectively.[53] A review of air sampling data from 149 commercial, urban buildings, where there were no health

complaints, demonstrated that viable fungal counts in indoor and outdoor ambient air averaged 233 CFU/m^3 (range: 17–1,212 CFU/m^3) and 983 CFU/m^3 (range: 92–2,061 CFU/m^3), respectively.[38] For 820 residential structures the indoor and outdoor ambient air average was 1,252 CFU/m^3 (range: 17–9,100 CFU/m^3) and 1,524 CFU/m^3 (range: 20–11,883 CFU/m^3), respectively. A yearlong study of ambient air in two homes in Yokohama, Japan demonstrated substantial variation in the number of CFUs depending on the media used and the time of year.[54] The arithmetic mean of airborne fungi in indoor air samples on dichloran 18% glycerol agar and potato dextrose agar was 252 ± 383 CFU/m^3 (range: up to 3,750 CFU/m^3) and 57 ± 136 CFU/m^3 (range: up to 1,875 CFU/m^3), respectively. The total culturable fungal count in outdoor air samples often exceeds 1,000 CFU/m^3, and the total fungal count may reach 10,000 CFU/m^3, particularly during summer months.[55] The clinical significance of average viable fungal CFU concentrations in indoor air samples above 1,000/m^3 should be interpreted cautiously because there are limited data correlating these measurements to specific diseases, and there is no definite dose-response relationship between specific ambient mold concentrations and human health effects.[29] Viable fungal spores in ambient air samples from a composting plant ranged from 10^3–10^4 CFU/m^3 in the storage area to 10^4–10^7 CFU/m^3 in the loading area.[56]

Generally, outdoor air concentrations of fungi are very low when snow is present on the ground.[57] Table 45.3 lists the colony counts of the common fungal general in indoor and outdoor air samples from a large US study.

The concentration of viable fungal genera in homes without excessive fungal growth is usually <1,000–2,000 CFU/m^3.[58,59]

TABLE 45.3. Total Colony-Forming Units for Common Fungal Genera in Positive Air Samples from a Large, Nonrandom US Study

Fungal Genera	Positive Samples (%)	Median Count (CFU/m^3)	95% Confidence Interval (CFU/m^3)
Cladosporium			
Indoor	86	40	12–480
Outdoor	92	200	18–1,849
Penicillium			
Indoor	80	30	12–570
Outdoor	77	50	12–377
Aspergillus			
Indoor	62	20	12–373
Outdoor	49	20	12–170

Source: Adapted from Ref 32.

A cross-sectional study of indoor air samples from buildings with occupant complaints suggested that total fungal counts exceeding 2,000 CFU/m^3 are associated with respiratory irritation (cough, rhinitis, sore throat), but health complaints did not correlate to air concentrations of fungi.[60] Some studies of workers associated the presence of *Aspergillus*[61] and *Penicillium*[62] with respiratory complaints, but a direct causal relationship was not established. In these two studies, the suspected agent was different despite the presence of both fungal genera in ambient air samples from the affected buildings. The quantitative value of CFUs must be interpreted cautiously because of the high variability of colony forming units over very short sampling periods and the small percentage of culturable spores compared with the total spore count.[63]

Total Spore Concentrations. The collection of noncultured, fungal propagules on a filter or sticky surface (e.g., Air-O-Cell cassette; Zefron, Inc., St. Petersburg, FL) allows the estimation of the total fungal mass (i.e., culturable and nonculturable) as measured in spores/m^3. Some fungi demonstrate distinctive spores, but the spores of many indoor fungal species (e.g., *Penicillium, Aspergillus*) are difficult to distinguish and characterizing fungi genera via gross microscopic features is unreliable. Consequently, total spore counts do not separate *potentially* toxic fungal species from nonmycotoxin-forming species because of the difficulty identifying the species of some spores. Disturbances of surface growth (i.e., wiping area of mold), dust control measures, pets, humidification, carpet type, and vacuum cleaning of carpets can cause large temporal increase in ambient air counts of spores. Comparison of indoor and outdoor spore samples must consider the number of samples and the season because of the variation of outdoor spore counts with vegetation, season, and weather. In particular, *Cladosporium* spore concentrations in outdoor air samples vary as much as 100-fold between summer and winter.[64]

A review of air sampling data from 47 commercial, urban buildings, where there were no health complaints, demonstrated total spore counts in indoor samples averaged 768 spore/m^3 (range: 610–1,040 spores/m^3), while total spore counts in outdoor samples ranges from 400–80,000 spores/m^3.[38] For 85 residential structures the indoor total spore count averaged 913 spores/m^3 (range: 68–2,307 spores/m^3), while the total spore count in outdoor samples ranges from 400–80,000 spores/m^3. The total fungal spore concentration in ambient air is substantially lower in moldy homes compared with some occupational environments (e.g., sawmills, composting facilities). The clinical significance of total spore concentrations in indoor air samples above 1,000/m^3 should be

interpreted cautiously because there are limited data correlating these measurements to specific diseases, and there is no definite dose-response relationship between specific ambient mold concentrations and human health effects.[29,65] In a study of 10 healthy sawmill workers, personal sampling methods demonstrated a mean total fungal spore count of 668,400 spores/m^3 (range: 215,000–1,460,000 spores/m^3).[66] Although some of these workers reported nasal and lower airway symptoms, there was no clear dose-response relationship between spore counts and symptoms. Comparison of proinflammatory mediators in nasal lavage fluid of these workers during exposure (work) and nonexposed (vacation) conditions demonstrated no significant difference. In a study of air concentrations of farms with and without adverse health effects (i.e., allergic alveolitis, organic dust toxic syndrome) the average total spore count on farms without complaints was 1.2×10^8 spores/m^3 (120 million/m^3).[67] The presence of numerous spores with mycelia indicates active mold growth.[68]

Water Damage and Mold Growth

Although species of *Penicillium* and *Aspergillus* are common molds present in most homes, most of these species do not produce mycotoxins. Consequently, the presence of fungal species from these genera does not necessarily imply the presence of mycotoxins, and the proper interpretation of air samples requires the identification of fungal species.[57] Furthermore, the presence of a mycotoxin-producing species does not necessarily imply the presence of mycotoxins because the conditions for growth of the mold are often different from the conditions necessary for the formation of mycotoxins. Water damage increases the concentration and growth of fungi depending on the individual growth requirements of the particular fungal species. The growth of fungi on building materials always occurs as a result of high water activity (a_w) at the surface of the material with the minimal a_w being approximately 0.67–0.75 depending on temperature, time, and material.[69] Fungal genera are divided into the following classification based on water activity: <0.8 (primary colonizers-*Wallemia, Penicillium, Aspergillus*, and *Eurotium*; 0.8–0.9 (secondary colonizers—*Cladosporium*), and >0.9 (tertiary colonizers—*Stachybotrys, Trichoderma, Fusarium, Chaetomium, Ulocladium, Alternaria*).[70] *Ulocladium* species usually does not produce mycotoxins.[34]

Table 45.4 lists mycotoxins produced from fungal species present in water-damaged buildings. Although these fungal species are capable of producing mycotoxins, the amount of mycotoxins present in these fungal

TABLE 45.4. Potential Mycotoxin-producing Fungi in Water-Damaged Buildings

Genus	Species	Mycotoxin
Alternaria	spp.	Altenuene, alternariol, iso-altenuene, alternariol mono ethyl ether, tenuazonic acid, altertoxins I & II
Alternaria	*tenuissima*	Alternariol,[a] alternariol mono ethyl ether,[a] tenuazonic acid, altertoxins I
Alternaria	*infectoria*	No known toxic metabolites
Alternaria	*alternata*	Alternariol, alternariol mono ethyl ether, tenuazonic acid, altertoxins I
Aspergillus	*fumigatus*	Fumitoxin, gliotoxin,[a] tryptoquivalins, verrucologen
Aspergillus	*niger*	Naphthopyrones, malformins A, B, C, nigragillin,[a] orlandin,[a] ochratoxin A
Aspergillus	*ochraceus*	Ochratoxin A, penicillic acid, xanthomegnin, viomellein, vioxanthin
Aspergillus	*ustus*	Austamide, austdiol, austocystins A & B, kotanin[a]
Aspergillus	*versicolor*	Sterigmatocystin,[a] 5-methoxysterigmatocystin,[a] versicolorin
Chaetomium	*globosum*	Chaetoglobosins A, B and C,[a] chetomin
Paecilomyces	*variotii*	Patulin, viriditoxin
Penicillium	*aurantiogriseum*	Auranthine, nephrotoxic glycopeptides, penicillic acid, verrucosidin
Penicillium	*brevicompactum*	Mycophenolic acid[a]
Penicillium	*chrysogenum*	Roquefortine C, meleagrin,[a] chrysogin,[a] ochratoxin
Penicillium	*expansum*	Chaetoglobosins A and C, communesins A and B, roquefortine C, citrinin, patulin[a]
Penicillium	*polonicum*	3-methoxyviridicatin,[a] nephrotoxic glycopeptides, verrucosidin,[a] normethylverrucosidin, penicillic acid, verrucofortine[a]
Stachybotrys	*chartarum*	Macrocyclic trichothecenes (satratoxins H,[a] G, F, iso-F, roridin L-2,[a] roridin E,[a] verrucarins J and B), esters of verrucarol and trichodermol, phenylspirodrimanes
Trichoderma	*harzianum*	Alamethicin, emodin, suzukacillin, trichodermin
Wallemia	*sebi*	Walleminol A and B

[a]Mycotoxins produced by fungal species grown on construction material. Although variable quantities of mycotoxins are produced by the fungal species above grown in culture, there are a limited number of mycotoxins produced by the growth of these fungal species on building materials.

species is highly variable depending on environmental conditions and the strain involved. Many strains of mycotoxin-producing species do not form mycotoxins. Most studies report the presence of the mycotoxin-producing fungi in samples from building material rather than from ambient air. The actual health risk to occupants from these water-damaged buildings is unclear because most known mycotoxins are nonvolatile,[71] and the development of mycotoxin-related disease would require the inhalation of an extremely large numbers of *airborne* mycotoxin-containing spores. The potential of mycotoxins to produce clinically significant diseases following inhalation depends on a variety of poorly defined factors including the volatility of the individual mycotoxins, the type of building materials,[72] the quantity of spores released into the air, and dose-response relationships for clinical effects. There are limited human data on the chronic health effects of exposure to low concentrations of mycotoxins in ambient air, and there is no definite clinical evidence that common concentrations of fungi in indoor air produce toxic effects.[73,74] Determination of a causal link between mycotoxins and respiratory disease requires the development of a sensitive assay for the specific mycotoxin; consequently, the evaluation of measurements of viable and nonviable spores in air samples must be interpreted cautiously. Studies of workers exposed to moldy, agricultural environments indicate that the inhalation of mycotoxins (e.g., ochratoxins) from ambient air is relatively small compared with dietary exposure to mycotoxins.[75]

Most fungal cell walls contain glucans, which are glucose polymers that are chemically bound to chitin. Common fungal genera that contain glucans [e.g., (1→ 3)-β-D-glucans] in the cell walls include *Alternaria*, *Aspergillus*, *Cladosporium*, and *Penicillium*. Although the exact role of these chemicals in human disease is unclear, the potent inflammatory properties of (1→3)-β-D-glucan suggest that the presence of this chemical in ambient indoor air may contribute to respiratory irritation and increased bronchial reactivity in sensitized individuals.[76,77] Normal background concentrations of (1→3)-β-D-glucan in ambient indoor air samples typically are below 5 ng/m^3 with values above this concentration associated with previous mold growth.[78] Houses with excessive mold growth may contain (1 → 3)-β-D-glucan concentration up to 100 ng/m^3.[79] However, the relationship between ambient concentrations of (1 → 3)-β-D-glucan and airway inflammation is complex. In a study of Swedish row houses, the baseline FEV_1 and the prevalence of respiratory symptoms did not correlate to the airborne (1 → 3)-β-D-glucan concentration either in atopic or normal individuals.[80]

TARGET ORGANS

Exposures to fungi are ubiquitous, and most healthy humans do not develop illness as a result of these exposures. The mechanisms of disease following these exposures include allergy, infection, and toxicity. Diseases associated with exposure to fungi include the following: 1) IgE-mediated hypersensitivity reactions (e.g., allergic rhinitis, allergic fungal rhinosinusitis, conjunctivitis, asthma, allergic bronchopulmonary aspergillosis), 2) hypersensitivity pneumonitis (non-IgE activation of Th1 lymphocytes), 3) infectious diseases (dermatophytes, *Blastomyces*, *Cryptococcus*, *Histoplasma*, *Coccidioides*, *Candida*), and 4) mycotoxicoses (organic dust toxic syndromes, aflatoxicosis, ochratoxicosis, ergotism).[81] Of the four types of reactions, Ig-E mediated hypersensitivity reactions are the most common. Although allergy to molds is not uncommon, mold exposure is a relatively minor cause of allergic reactions because most of these individuals demonstrate allergic responses to multiple allergens (e.g., dust mites, animal dander, house dust, pollens).[82] Hypersensitivity pneumonitis (IgG-mediated immune-complex response to pet birds, contaminated humidifiers, compost, moldy tobacco, cheese, moldy hay, moldy grapes, moldy dust) and IgE-mediated response to fungal growth in the host (allergic bronchopulmonary aspergillosis, allergic fungal sinusitis[83]) are rare forms of mold-related allergic diseases. A few outdoor fungi (*Blastomyces, Coccidioides, Cryptococcus, Histoplasma*) potentially cause serious systemic diseases as a result of the invasion of immunocompetent hosts. Other fungi or dermatophytes (*Tinea* spp., *Candida albicans*) may produce superficial infections, but most fungi in general do not produce serious systemic illness except in seriously immunocompromised patients. Organic dust toxic syndromes are a heterogeneous group of lower respiratory illnesses manifest by fever, chills, malaise, headache, myalgias, nonproductive cough, and dyspnea. Pulmonary function tests and chest radiographs are usually normal, and symptoms typically resolve within 48 hours of exposure. The high airborne concentrations of spores causing the organic dust toxic syndrome are unlikely to occur in home, school, or office environments.[67]

Most data linking mycotoxins with human disease result from extrapolation of animal data and limited human epidemiological data. Mycotoxins potentially may produce toxicity in numerous organ systems, particularly after the ingestion of mycotoxin-contaminated food stuffs. However, causal links between mycotoxins and human illness are limited because of the lack of direct methods to assess mycotoxins in indoor air, and the lack of validated clinical biomarkers for mycotoxin-induced illness. Additionally, there is no unequivocal

evidence that the inhalation of mycotoxins produces illness in human inhabitants of dwellings that contain common molds. Modeling of airborne exposure to mycotoxins indicates that the delivery of mycotoxins via inhalation of mold spores is very inefficient, and unrealistic high airborne spore levels over extended periods of time are necessary to elicit a response.[84] Consequently, the associations between nonspecific human complaints (headache, nausea, vomiting, diarrhea, memory loss, weakness, moodiness, cough, rhinorrhea, cough, epistaxis) and mycotoxins are speculative.[81]

Liver

The ingestion of aflatoxins is a potential cause of acute hepatocellular disease and hepatocarcinoma in humans in developing countries. There are inadequate human data to link aflatoxins with illness in developed countries. Other animal hepatotoxins associated with mycotoxins include sporidesmin,[85] rubratoxin,[86] and ochratoxin.[87] Sporidesmin is a secondary metabolite of the saprophytic fungus, *Pithomyces chartarum* (Berk. & M.A. Curtis) M.B. Ellis. This fungus grows on dead pasture litter, particularly perennial rye grass.

Kidney

Both citrinin and ochratoxin A are nephrotoxic in pigs. High dietary intake of ochratoxin A occurs in geographic areas where Balkan nephropathy is endemic.[88] However, the contribution of ochratoxin A to the development of this disease in humans remains undefined.

Hematological and Immune System

Pancytopenia occurs in alimentary toxic ataxia together with hemorrhage and ulceration of the alimentary tract mucosa. A similar disease known as stachybotryotoxicosis occurs in horses, which consume moldy hay. Aflatoxin B_1 is a recognized human carcinogen, although the exact role of this mycotoxin in the development of cancer in humans remains undefined. The IARC lists fumonisin and ochratoxin A as possible carcinogens, but there are inadequate data to link these mycotoxins with cancer in humans.

Onyalai is a common cause of thrombocytopenic purpura in Africa. The consumption of mold-contaminated millet may contribute to the development of this disease. Experimental studies suggest that the ingestion of a mycotoxin from *Leptosphaeria sacchari* Breda de Haan [*Phoma sorghina* (Sacc.) Boerema, Dorenb. & Kesteren] may predispose these patients to onyalai, but there are inadequate epidemiological data for a causal connection.[89] Mycophenolic acid is a toxic metabolite formed by *Penicillium brevicompactum* Dierckx and several other species of the genus *Penicillium*. This mycotoxin causes a significant reduction of the intracellular guanine nucleotide pools by reversibility inhibiting inosine monophosphate dehydrogenase, which is the enzyme that catalyzes the first step in the synthesis of guanosine monophosphate.[90] This action causes immunosuppression by inhibiting T and B cell lymphocyte proliferation and function. The prodrug mycophenolate mofetil, which is the morpholinoethyl ester of mycophenolic acid, is approved by the US Food and Drug Administration (FDA) for the prevention of rejection in patients with allogeneic renal transplants.[91] An intentional overdose of 10 g mycophenolate produced only mild gastrointestinal distress with no hemodynamic, hepatic, renal, or hematologic toxicity.[92]

Cardiac and Nervous Systems

Citreoviridin is a mycotoxin isolated from a penicillin mold (*Penicillium citreonigrum* Dierckx) that grows on yellow rice during storage after harvest, particularly in the colder regions of Japan.[93] The administration of this mycotoxin to animals causes paralysis, convulsions, and cardiac failure. A similar human disease known as cardiac beriberi occurred during the 17th and 18th centuries in Japan and other Asian countries. Disappearance of this entity coincided with improved farming practices and the implementation of government programs to inspect rice. Sporadic outbreaks of cardiac beriberi (yellow rice disease, Shoshin-kakke disease) occurred after the consumption of decomposing rice contaminated with toxigenic *Fusarium* species (yellow rice toxins).[94] However, there are inadequate epidemiological data to causally link this disease with citreoviridin. There have been no outbreaks of yellow rice disease in the last several decades.[1]

Moldy sugarcane poisoning results from the ingestion 3-nitropropionic acid (3-NPA), which is a metabolite of the *Arthrinium* species present in moldy sugarcane during prolonged storage.[95] The ingestion of 3-NPA causes gastrointestinal symptoms in adults, but a severe encephalopathy was associated with 3-NPA ingestion by children.[96] The incubation period is about 2–3 hours with symptoms including nausea and vomiting that progress to dystonia, dysconjugate gaze, carpopedal spasm, and coma.

Skin

The trichothecene mycotoxins produce photosensitivity dermatitis along with hemorrhage and vesiculation followed by desquamation when applied to the skin of experimental animals. Similarly, photosensitizing furo-

coumarins (xanthotoxin, bergapten) are produced by the pink rot fungus, *Sclerotinia sclerotiorum* (Lib.) de Bary, which grows in celery.[97,98]

Reproductive System

Zearalenone (F-2 toxin) is a naturally occurring, nonsteroidal, estrogenic product of *Fusarium* species that causes vulvar and uterine enlargement in animals. This toxin has not produced documented adverse effects in humans.

Respiratory Tract

Stachybotrys chartarum (Ehrenb.) S. Hughes (*S. atra*) was isolated from homes of infants, who developed idiopathic pulmonary hemorrhage, and from buildings where occupants complained of building-related upper respiratory tract symptoms. The presence of mycotoxins in these cases was not confirmed; therefore, the association of these illnesses with mycotoxins remains speculative. Although the intratracheal instillation of *S. chartarum* spores produces a dose-dependent pulmonary inflammation,[99] no significant pulmonary damage occurs when mice are exposed to *S. chartarum* on moldy surfaces despite airflow at least 4 times greater than the airflow in a typical household.[100] Presently, there are inadequate data to support a causal connection between exposure to *Stachybotrys* mycotoxins and serious or permanent lung injury.[101]

Most mold-related respiratory disease is reversible.[66,102] Atopic individuals may develop allergic rhinitis, hypersensitivity pneumonitis, and asthma following exposure to mold. The prevalence for positive skin tests to mold in the general asthmatic population is approximately 5% with sensitization to fungi high in childhood and declining rapidly with age.[103] Relating mold exposure and mold sensitization to the risk of developing asthma is difficult because most individuals with specific sensitization to mold also are sensitized to other inhaled allergens (mites, house dust, pet dander). In addition, exposure of sensitized individuals to dust mites and to mold produces similar upper respiratory tract symptoms, and these two allergens frequently occur together.[104] Cross-sectional and prevalent case-control studies suggest that mold exposure based on questionnaires (visible mold, moldy odor) is associated with a slightly increased risk (mean OR <1.5) of asthma.[105,106]

Musculoskeletal System

Kashin-Beck Disease is a chronic, bilateral osteoarthritis believed to result from inadequate perfusion of the epiphyses.[107,108] The main feature of this disease is shortened stature, which results from multiple focal necroses in the growth plate of tubular bones. The disease occurred in Eastern Russia among the Cossacks during the 19th and early 20th centuries, but reports of the disease now originate exclusively from China. Mycotoxins from *Fusarium sporotrichiella* Bilai are suspected cofactors along with selenium deficiency, but there is insufficient epidemiological evidence to confirm this association.

EVALUATION MOLD-RELATED COMPLAINTS

Table 45.5 outlines the approach to a patient with complaints related to indoor mold exposure.[109] The medical

TABLE 45.5. Approach to the Evaluation of Mold-Related Complaints

Method	Components
Comprehensive Medical History	Symptoms onset, progression, persistence, exacerbation, improvement, resolution; medical and drug (licit, illicit) history, family history (allergies, related diseases)
Environmental History	Onset/duration of odors, water leaks (outside, roof, plumbing), ventilation (air/heat, temperature settings, humidifiers, vaporizers, purifiers), visible mold growth, pets (cats, birds), home use (use patterns, temperature settings, plants), hobbies and outdoor activities (camping, gardening, composting)
Occupational History	Symptoms at work, exposure to dusts, fumes, chemicals, particulate matter
Physical Examination	Complete examination to detect objective signs of disease
Diagnostic Testing	Chest x-ray, serologic testing (serum immunoglobulins, total IgE, rheumatoid factor, complete blood count, sedimentation rate, C-reactive protein, serological testing for specific IgG and IgE to fungi (radioallergosorbent test [RAST], skin testing, hypersensitivity panels), spirometry (pre- and postbronchodilator measurements), serum chemistry panel
Environmental Survey	Inspection of building (HVAC system, filters, ceiling tiles gypsum wallboard, paper/cellulose-containing surfaces), collection and analysis of airborne samples from appropriate inside and proximal outside locations

history is an important component of the evaluation, particularly relating the temporal onset and resolution to exposure in the building. The physical examination and diagnostic tests provide potential alternate explanations for the symptoms, correlate symptoms to objective evidence of disease, and determine exposure to specific molds. The extent of diagnostic testing depends on the mold and the organ systems involved with the complaints. Additional testing (e.g., CT sinuses, fungal IgE titers, methacholine challenge, neuropsychological testing, nerve conduction studies) may be important depending on the type and severity of complaints. Environmental surveys help determine the source of exposure based on inspection and collection of air samples from locations inside the building. An equal number of samples should be collected simultaneously from an area immediately outside the indoor location of sampling.

AFLATOXINS

HISTORY

Isolation of the first aflatoxins occurred in 1959. In the early 1960s, aflatoxin was a recognized animal carcinogen, when Turkey X disease was associated with the consumption of rosetti, an aflatoxin-contaminated groundnut meal from Brazil, by turkeys.[110]

PRINCIPAL TOXINS

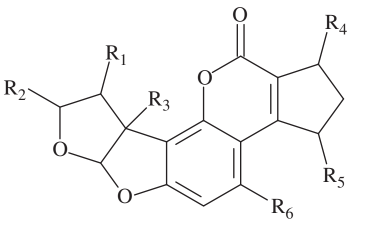
Structure

Aflatoxins are highly substituted difuranocoumarin derivatives that contain an unusual fused dihydrofurofuran configuration. These mycotoxins are divided into two major groups based on their blue or green fluorescence under UV light (see Figure 45.1). The four major aflatoxins are the difurocoumarocyclopentenones B_1 [CAS No. 1162-65-8] and B_2 [CAS No. 7220-81-7], and the difurocoumarolactones G_1 [CAS No. 1165-39-5] and G_2 [CAS No. 7241-98-7]. Aflatoxins are densely fluorescent with the B referring to blue fluorescence and G signifying green fluorescence. The subscript numbers 1 and 2 indicate major and minor compounds, respectively. B_1 is the most potent and most common aflatoxin.[6] The other major aflatoxins are usually not present in the absence of B_1. M_1 (CAS No. 6795-23-9) and M_2 aflatoxins are active 4-hydroxylated metabolites present in milk and urine following the consumption of aflatoxins B_1 and B_2. Sterigmatocystin is a 7,8-dihydrofuro[2,3-β]furan, which is a precursor of aflatoxins found primarily in *A. versicolor* (Vuill.) Tirab. and *Emericella nidulans* (Eidam) Vuill. (*Aspergillus nidulans*). Cyclopiazonic acid is an indole-tetrameric acid mycotoxin found most commonly in *A. flavus*.

Physiochemical Properties

Aflatoxins are slightly soluble in water. The lactone ring in aflatoxins is susceptible to alkaline hydrolysis.

Aflatoxin B_1 and its derivatives



Aflatoxin	R_1	R_2	R_3	R_4	R_5	R_6

EXPOSURE

Source

About one-half of the strains of *Aspergillus flavus* Link produce aflatoxins B_1 and B_2, while *A. parasiticus* Speare and *A. nomius* Kurtzman, B.W. Horn & Hesselt. produce aflatoxins G_1 and G_2 in addition to B_1 and B_2.[111,112] Other less common aflatoxin-producing *Aspergillus* species include *A. bombycis* S.W. Peterson, Yoko Ito, B.W. Horn & T. Goto, *A. ochraceoroseus* Bartoli & Maggi, and *A. pseudotamari* Yoko Ito, S.W. Peterson, Wicklow & T. Goto. Aflatoxins M_1 and M_2 are hydroxylated metabolites of aflatoxins B_1 and B_2 that occur in milk or milk products after livestock ingest contaminated feed (groundnut meal, maize, cottonseed meal). *A. flavus* Link is a ubiquitous fungus that contaminates plants and plant products, whereas *A. parasiticus* Speare is less widely distributed. *A. nomius* Kurtzman, B.W. Horn & Hesselt. probably does not contribute significantly to the health impact of aflatoxins because this species is relatively rare.[19] Aflatoxin-producing strains of *Aspergillus* generally produce 2–3 aflatoxins, one of which is always aflatoxin B_1. Usually, these toxic strains produce substantially smaller amounts of aflatoxin $G_1$and G_2.[113] The presence of aflatoxin-producing *Aspergillus* species does not imply the presence of mycotoxins because not all of these strains produce aflatoxins. Approximately 30% (range: 20–98%) of *Aspergillus flavus* Link strains produce aflatoxins.[114] The use of heroin may increase the risk of exposure to aflatoxins. In a study of urine samples from 121 European heroin addicts, aflatoxins contaminated 20% of the urine samples of the heroin addicts compared with 2% of the urine samples from healthy volunteers.[115]

Environmental Conditions

Aflatoxin-producing *Aspergillus* species have an affinity for nuts, maize, and oilseeds. Various factors affect the rate of aflatoxin production. Ideal conditions for aflatoxin formation include moisture content between 18–20%, adequate amounts of zinc, and ambient temperature between 25 °C–40 °C (77 °F–104 °F).[110] Minimum environmental conditions for the production of aflatoxins include water activity >0.82, pH 3.0–8.5, and temperature 12 °C–40 °C (~54 °F–104 °F).[15] Other nutrition factors affecting the production of aflatoxins include carbohydrate and nitrogen sources, phosphates, lipoperoxide, and other trace metals.[116]

Inadequate drying or improper storage promotes the development of aflatoxins in humid climates. Significant concentrations of aflatoxins develop as a result of post-harvest spoilage of aflatoxin-contaminated commodities stored under warm conditions. In temperate climates, the invasion of susceptible crops (maize, nuts) by *A. flavus* before harvest contributes to the production of aflatoxins, particularly during periods of drought stress and insect invasions.[117] Small grain cereal spoilage by *A. flavus* is uncommon in the absence of poor handling.[19] Effective measures to limit the formation of aflatoxins include storage of crops in cool, dry, insect-free environment, harvesting of crops during the dry season with adequate drying, and prevention of chemical and insect damage to crops.[110] Soybeans rarely contain aflatoxin because of the presence of a strong zinc-chelating agent, phytic acid.[118]

Foodstuffs

Maize, cotton seed, and groundnuts (e.g., peanuts) are the major source of aflatoxins, particularly in India, South America, and the Orient.[119] Specific foodstuffs commonly contaminated by aflatoxins include topical and subtropical cereals, cassava, dried fish, rice, oilseeds, cotton-seed meal,[120] peanuts, Brazil nuts, and pistachios. Of the major grains used for human consumption in the United States (i.e., wheat, rye, oats, corn), significant aflatoxin contamination occurs only in corn. Contamination of peanuts occurs periodically in the Southeast; however, most of these products do not reach interstate commerce. Herbs and spices may contain relatively low aflatoxin concentrations (<10 μg/kg) compared with maize and groundnuts.[121] A study of dried-salted fish samples from markets in Sri Lanka demonstrated the presence of *Aspergillus flavus*, but these strains did not produce aflatoxins.[122]

Although wet and dry milling processes fractionate the aflatoxin between the germ, steep water, and the hull/fiber, these processes do not destroy significant quantities of the aflatoxin.[123] Aflatoxins are relatively heat-stable during the preparation of foods (e.g., boiling, autoclaving, microwave). Domestic cooking with microwave and conventional gas ovens does not reduce the aflatoxin concentration in contaminated food products. In an experimental study, roasting eliminated about 50% of the aflatoxin B_1 present in peanuts.[124] In general, aflatoxin ingestion is very low in the United States and Europe compared with developing countries. Although local beers brewed in Africa contain substantial amounts of aflatoxins, these mycotoxins are rare contaminates of European and North American beers.[125] In a study of 24 beer samples from the United States and Mexico, only one sample of Mexican beer contained aflatoxins at a concentration of 49 ng aflatoxin B_1/L.[126]

DOSE RESPONSE

A deliberate ingestion of 1.5 mg/kg of aflatoxin by a 25-year-old woman over approximately 2 weeks resulted in a transient nonpruritic macular rash, headache, and nausea, but no sequelae were detected during a follow-up examination 14 years later.[127] Maize grain samples from two Kenyan homes where 8 people died of hepatic failure revealed aflatoxin B_1 levels of 12 ppm and 3.2 ppm, while samples from unaffected homes had maximum aflatoxin B_1 concentrations of 0.5 ppm.[128] The estimated daily consumption of aflatoxins during an epidemic of acute hepatitis associated with aflatoxin consumption was 2–6 mg.[9]

TOXICOKINETICS

Absorption

Although few quantitative data on aflatoxin absorption exist, animal and human cases associated with aflatoxin to date involve ingestion rather than other routes of exposure. Experimental studies indicate that the dermal absorption of aflatoxin B_1 is slow and toxicologically insignificant.[129]

Biotransformation

The cytochrome P450 (CYP450) isoenzyme system in the liver metabolizes aflatoxin B_1 primarily via hydroxylation. The human CYP450 isoforms, CYP3A4 and CYP1A2, catalyze the epoxidation reaction of aflatoxin B_1 to aflatoxin B_1 exo-8,9-epoxide.[130] Oltipraz is a potential inhibitor of this epoxidation reaction.[131] This epoxide is highly unstable with a high affinity for the formation of adducts to guanine bases in DNA (i.e., aflatoxin-N^7-guanine). CYP1A2 also catalyzes the formation of the metabolite aflatoxin M_1. The most common metabolites of this biotransformation are aflatoxin M_1, which retains some acute oral toxicity in contrast to most other aflatoxin metabolites, and aflatoxin Q_1 (see Figure 45.2) Other metabolites of aflatoxin B_1 include aflatoxin P_1, aflatoxin B_2 , aflatoxicol, aflatoxicol H_1, aflatoxin B_1-2,3-dihydriol, and the unstable, reactive metabolite, aflatoxin B_1-2,3-epoxide. In general, <6% of the aflatoxin B_1 present in animal feed is converted to aflatoxin M_1 in milk.[111]

There is substantial variation in aflatoxin metabolism between species, and this difference probably accounts for the variable response of different species to aflatoxin-induced carcinogenesis. The formation of aflatoxicol from aflatoxin differs from other pathways of aflatoxin metabolism because of the requirement for cytoplasmic NADH-dependent dehydrogenase, which is sensitive to sex hormones. Such metabolic differences may account for some of the variation in response to aflatoxins between sexes (children and men are more susceptible) and species (rats highly sensitive, humans much less sensitive, mice least sensitive).[132]

Elimination

Renal excretion of aflatoxin M_1 (AFM_1) occurs after the ingestion of aflatoxin B_1,[133] but there are few human data on the toxicokinetics of aflatoxins or the relative amount of M_1 eliminated in human urine. In a study of

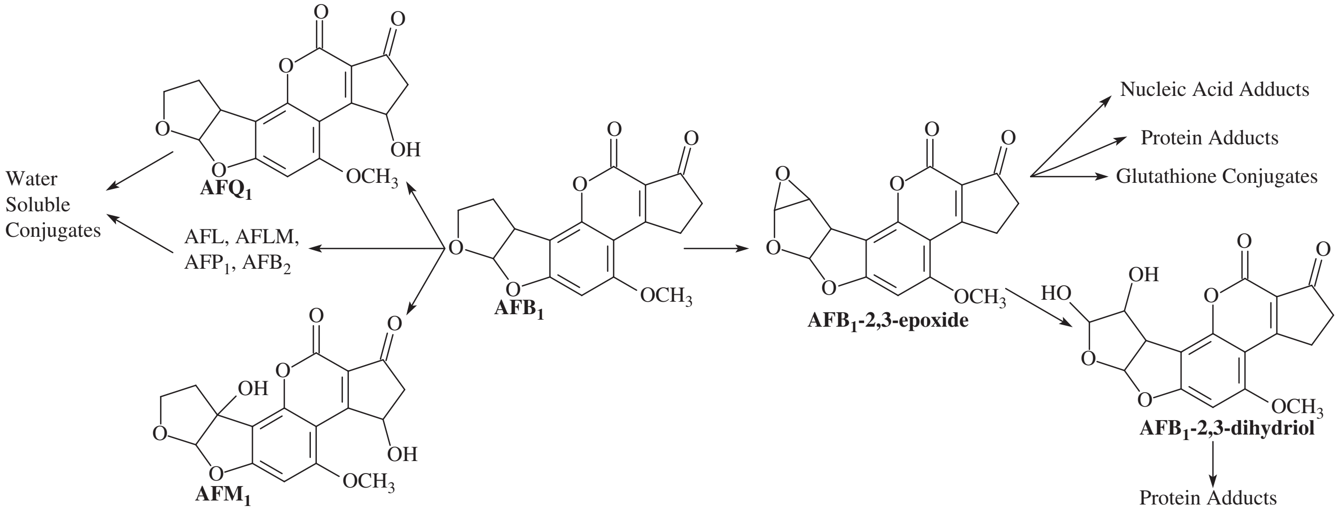

FIGURE 45.2. Aflatoxin B_1 (AFB_1) Metabolism. Reduction of AFB_1 by cytoplasmic reductase produces aflatoxicol. Hydroxylation of AFB_1 forms AFQ_1 and AFM_1. *O*-demethylation of AFB_1 produces AFP_1. AFB_2 results from the hydration of AFB_1. Adapted from Denning DW. Aflatoxin and human disease. Adv Drug React Action Poison Rev 1987;4:178.

Chinese residents ingesting aflatoxins in corn and peanut oil, the renal excretion of AFM_1 accounted for about 1–2% of the dose of aflatoxin B_1 (AFB_1).[134] There is substantial variation in the urinary excretion of M_1 between different species. Aflatoxin M_1 is a minor urinary metabolite in monkeys,[135] whereas biliary excretion accounts for the majority of the absorbed dose of AFB_1 in rats. Animal studies indicate that the elimination of AFB_1 from the blood is rapid. Following the intravenous administration of 0.3 mg AFB_1/kg to monkeys, the plasma half-life of AFB_1 was approximately 36 minutes.[136] Fecal and renal excretion each accounted for the elimination of about one-third of the administered dose of AFB_1 in monkeys. Biliary excretion accounts for a substantially larger part of the elimination of aflatoxins in rodents than in monkeys.[136] In monkeys, about 80% of the administered dose of AFB_1 was eliminated within 1 week, but some radiolabeled AFB_1 remained in the blood and urine after 5 weeks.[137] A study of cord blood in Thailand infants suggests that transplacental transfer of aflatoxins occurs, and that aflatoxin concentrations may be higher in the placenta than in the maternal serum.[138]

HISTOLOGY AND PATHOPHYSIOLOGY

The most biologically active aflatoxins are aflatoxins B_1 (AFB_1) and aflatoxin G_1 (AFG_1). The liver is the main target organ of aflatoxins in animals, and animals fed high doses of aflatoxins usually develop hepatic necrosis. Characteristically, aflatoxins produce proliferation of the bile duct epithelium, fatty infiltration, and centrilobular necrosis.[139] The carcinogenic potential of aflatoxin probably depends on the metabolic activation of AFB_1 or other aflatoxins to DNA alkylating agents, such as the AFB_1-2,3-epoxide.[28] Aflatoxin B_1 reduces hepatic glycogen stores and causes the accumulation of hepatic lipids in experimental animals.[140] Aflatoxin B_1 strongly inhibits the salt-induced conversion of the right-and left-handed DNA forms. These DNA configurations may be associated with regulation of gene function; therefore, aflatoxin-induced changes in DNA equilibrium may cause permanent transcriptional changes as well as interfering with RNA synthesis via inhibition of RNA polymerase.[139] The main adduct formed by AFB_1 occurs at the 2-position of AFB_1 and the N-7 position of guanine in the DNA.

In experimental animal models, AFB_1 interferes with acquired immunity to *Pasteurella multocida* (Lehmann & Neumann 1899) Rosenbusch and Merchant, and this aflatoxin suppresses delayed cutaneous hypersensitivity, lymphokine activity, graft-versus-host reaction, phagocytic response to macrophages, and complement activity. Rather than act as a primary carcinogen, aflatoxin may suppress cell-mediated immunity and therefore increase the number of hepatitis B virus carriers. Other potential contributing factors to the carcinogenic potential of aflatoxins include chronic protein-deficiency and essential malnutrition associated with acquired immunocompetence syndrome.[141–143]

CLINICAL RESPONSE

Acute

Determining the exact cause of human illnesses associated with mycotoxins is difficult because of the lack of a suitable biomarker of exposure. Generally, reports use indirect measures of exposure (e.g., analysis of common foods) rather than direct measures of aflatoxin exposure. Reports of acute toxicity secondary to aflatoxins (aflatoxicosis) are rare, and these reports usually involve acute outbreaks of hepatitis. Because of the nonspecific symptoms associated with aflatoxicosis, outbreaks generally involve communities rather than individuals. Outbreaks of aflatoxicosis often occur in tropical countries among undernourished adults in rural populations that use maize as the staple food. In India during 1974, the consumption of maize containing aflatoxin concentrations of 6–15 µg/kg was associated with 397 cases of acute hepatitis.[9] Clinical features included jaundice, severe ascites, portal hypertension and death secondary to massive gastrointestinal bleeding. There were 106 deaths. A similar epidemic of acute hepatitis was reported in several Kenyan homes after the consumption of corn heavily contaminated with 3.5–12 ppm aflatoxin.[128] Although substantial mortality may occur during the acute phase of aflatoxicosis, follow-up studies indicate that the hepatic inflammation usually resolves without persistent jaundice.[144] An estimated ingestion of 1.5 mg aflatoxin/kg over 2 weeks was associated with headache, nausea, and a nonpruritic rash, but there was no documented liver disease at follow-up 14 years after the incident.[127] This case report suggests that the hepatotoxicity of aflatoxins may be less in well-nourished patients than in malnourished patients.

Chronic

The causal link between aflatoxin exposure and Reye's syndrome (acute encephalopathy with fatty degeneration of the viscera and particularly the liver) is speculative. There are pathological similarities between Reye's syndrome and experimental aflatoxin poisoning. However, most cases of aflatoxin-associated Reye's disease appear in Thailand and not in countries (e.g.,

Africa) where aflatoxins commonly contaminate food. Elevated aflatoxin levels in kwashiorkor probably result from aflatoxin exposure and the inability of the malnourished liver to metabolize the aflatoxins rather than from a direct toxic effect.[145] Few human data causally link liver cirrhosis with aflatoxin exposure.

Carcinogenesis

Both the US National Toxicology Program[146] and the International Agency for Research on Cancer (IARC)[147] recognize naturally occurring aflatoxins as human carcinogens. Animal studies indicate that the carcinogenic activity of aflatoxin B_1 requires activation of this aflatoxin by the cytochrome P450 enzymes to aflatoxin B_1-8,9-epoxide.[111] Aflatoxin B_1 is a potent carcinogen in animal species, but there is a wide variation in the carcinogenic response between different animal species. The carcinogenic potency of aflatoxin B_1 is three orders of magnitude greater in rats than in mice.[148] In animal models, exposure to aflatoxin B_1 produces tumors primarily in the liver, colon, and kidneys, and there is sufficient evidence for carcinogenicity for aflatoxins B_1, G_1, and M_1. Aflatoxin B_2 is substantially less potent in animal studies than these later hepatocarcinogens. The IARC lists the metabolite, aflatoxin M_1, as a possible human carcinogen (Group 2B).

Aflatoxin and hepatitis B are co-carcinogens and the presence of both factors in developing countries is associated with a high incidence of hepatocellular cancer compared with developed countries where these factors are uncommon. A cohort study in China detected statistically significant excess mortality from liver cancer in villages with heavy aflatoxin contamination. However, primary hepatocellular carcinoma is one of the most common cancers of developing countries where mycotoxins, hepatitis B virus, malnutrition, and parasitic infections are frequent confounding variables for epidemiological studies of liver cancer.[141] Several correlation studies from Swaziland and China indicated that the incidence of liver cancer correlated more to aflatoxin exposure than to hepatitis B viral infection. However, there was no correlation between the presence of urinary aflatoxin metabolites and the incidence of liver cancer. Aflatoxins probably do not contribute significantly to the development of liver cancer in developed countries because of the absence of cofactors, such as endemic hepatitis B infections.[149] A retrospective study of mortality data comparing US regions with differing aflatoxin exposure demonstrated a slight excess of age-adjusted mortality from primarily liver cancer despite dramatic differences in aflatoxin consumption.[150]

DIAGNOSTIC TESTING

Analytical Methods

Thin-layer chromatography is the most economical method for the detection of aflatoxins with limits of quantitation in the range 0.2–10 ng/g depending on the extraction solvent and clean-up procedures.[151] Aflatoxins are highly fluorescent and bidirectional high performance thin-layer chromatography achieves detection limits below 1 μg/kg.[152] High performance liquid chromatography (HPLC) coupled with postcolumn iodine derivatization and fluorescence detection is more sensitive and accurate than thin-layer chromatographic techniques with limits of detection near 1 ppb.[153,154] Commercial immunoassays for aflatoxins are available for determining the presence of aflatoxins,[155] but the limits of detection are above current regulatory concentrations.[156]

Biomarkers

The short half-life of aflatoxin B_1 limits the usefulness of this substance as a biomarker. Excretion of the metabolite, aflatoxin M_1, in milk may result from the presence of aflatoxin B_1 in animal feed. Suggested conversion ratios for aflatoxin B_1 in feed to aflatoxin M_1 in milk ranged from 66:1 to about 300:1.[158] In a study of children from Sierra Leone, the urinary concentrations of aflatoxin B_1 and aflatoxin M_1 ranged from 0.04–319 ng/mL and 0.1–374 ng/mL, respectively, with the urine concentration of aflatoxin B_1 being significantly greater during the dry season.[157]

Health agencies in most countries set permissible aflatoxin B_1 exposure limits at 5 μg/kg. In the United Kingdom, the limit for aflatoxin B_1 in nuts, dried figs, and products used for direct human consumption is 4 μg/kg; the limit is 10 μg/kg if further processing reduces aflatoxin concentrations.[158] Foodstuffs contain aflatoxins because of the ubiquitous nature of aflatoxin-producing fungal species. Current FDA guidelines limit aflatoxin levels to 20 ppb in all animal feed crops except cottonseed meal for which the limit was recently raised to 300 ppb. Aflatoxin M_1 levels in milk are restricted to levels below 0.5 ppb. Serum and urine aflatoxin B_1 concentrations are not reliable biomarkers of chronic aflatoxin exposure because of the rapid elimination of aflatoxin B_1 from the blood and urine.

TREATMENT

Management for exposure to aflatoxins is supportive along with reduction of aflatoxin exposure. Good cultivation and storage techniques represent the best method of reducing aflatoxin levels in food. In the United States, the FDA monitors interstate food shipments (e.g., peanuts, corn, pecans, walnuts) for aflatoxin concentrations. Under experimental conditions, activated charcoal avidly binds aflatoxins.[159] Alkaline conditions also destroy mycotoxins.

CITRININ

Citrinin (CAS No. 518-75-2) is a water-insoluble mycotoxin produced by a variety of genera including *Penicillium* (*P. canescens* Sopp), *P. chrzaszczii* K.M. Zalessky, *P. citreosulfuratum* Biourge, *P. citrinum* Thom, *P. claviforme* Bainier, *P. expansum* Link, *P. implicatum* Biourge, *P. lividum* Westling, *P. phaeojanthinellum* Biourge, *P. purpurascens* (Sopp) Biourge, *P. roqueforti* Thom, *P. velutinum* J.F.H. Beyma, *P. verrucosum* Dierckx, *P. viridicatum* Westling) and *Aspergillus* (*A. candidus* Link), *A. flavipes* (Bainier & R. Sartory) Thom & Church, *A. terreus* Thom) species.[160] This toxin was first isolated from *Penicillium citrinum* Thom in 1931. Although *P. citrinum* is the main source of citrinin, several other *Penicillium* species (*P. expansum* Link, *P. verrucosum* Dierckx) also produce relatively high concentrations of this mycotoxin. *P. citrinum* grows in a wide temperature range from 5 °C–40 °C (41 °F–104 °F) with an optimum growth rate between 26 °C–30 °C (~79 °F–86 °F) and a minimum water activity 0.80–0.83.[15] The optimum production of citrinin occurs at 30 °C (86 °F; range: 15 °C–37 °C/~59 °F–99 °F). Citrinin-producing fungi grow on cereals, peanuts, and fruits stored in high humidity, but the presence of these fungal species does not necessarily indicate the presence of citrinin. This mycotoxin occurs naturally in barley, oats, rye, and wheat grown in North American and Europe. Food processing destroys most citrinin and this mycotoxin does not survive the mashing stem in the beer-brewing process.[125] Renal damage in experimental rats is the most common pathological lesion reported after exposure to citrinin.[161] Despite more than 30 years of clinical research, the role of citrinin as a human toxin or food contaminant remains unclear. There are no well-documented cases of citrinin-induced illness in humans.

ERGOT and RELATED COMPOUNDS

HISTORY

Historically, the first recognized mycotoxicoses were human diseases produced by the consumption of rye products infected by the mold *Claviceps purpurea* var. *purpurea* (Fr.) Tul. and related fungi. As early as 600 BC, Assyrian tablets referred to the "noxious pustules in the ear of grain," and one of the sacred books of the Pharisees (400–300 BC) mentioned "grasses that cause pregnant women to drop the womb and die in childbirth."[162] At that time, the consumption of contaminated rye was discouraged as "the black malodorous product of Thrace and Macedonia." However, these taboos were lost during Roman times because rye products were not part of the Roman diet. The first written accounts of ergotism occurred during the Middle Age in Europe, when thousands of fatalities resulted from epidemics of ergotism.

From the 9th–19th centuries, recurrent epidemics of ergotism plagued Germany, France, Scandinavia, and other parts of Europe both as a gangrenous (chronic) disease and as a convulsive (acute) disorder.[163] The more widely recognized affliction was the gangrenous type characterized by severe hypesthesia, paresthesias, and hemorrhagic bullae that progressed to dry gangrene and black mummification of the involved extremity. The descriptive term, holy fire *(ignis sacer*, St. Anthony's Fire) was given to this malady. St. Anthony was the patron saint for an Order of Hospitallers, founded in Vienne, France in 1095. Although St. Anthony was a 3rd century (251–356 AD) Egyptian ascetic with no direct connection to ergotism, these hospitals became pilgrimage centers for victims of ergotism. The diets at these hospitals probably did not contain rye infected with the mold *Claviceps*.

The less common type of ergotism was described as a convulsive syndrome and included symptoms such as vertigo, headache, tinnitus, sensual disturbances, hallucinations, muscle spasm, gastrointestinal distress, and seizures. One of the ergot alkaloids, isoergine (lysergic acid amide), has approximately one-tenth of the hallucinogenic properties of the structurally related compound LSD (lysergic acid diethylamide). Morning glory seeds contain the same alkaloid, and these seeds were used by the Aztec Indians as a ceremonial hallucinogen. Geographical differences in alkaloid production and host susceptibility probably accounted for the variation in expression of these two syndromes.

Growing conditions and agricultural practices in late 17th century New England favored the growth of *Claviceps* mold. Caporael suggested that ergotism may explain the physical afflictions and vivid imagery offered at the Salem Witchcraft Trials from 1691 to 1692.[164] The last European outbreak of ergotism occurred in the United Kingdom and in Russia during the late 1920s.[337] Improved agricultural and storage practices have virtually eliminated epidemic ergotism, although sporadic epidemics occur occasionally in less-developed countries. The last sporadic episode of ergotism involved a five-case outbreak in France in 1951.[165] Currently, ergotamine toxicity usually results in vascular insufficiency caused by excessive, chronic consumption of ergot alkaloids by patients with a history of migraine headaches. Acute massive overdose is rare.

Although ergot was a suspected cause of epidemics as early as 1677, the presence of ergot alkaloids in parasitic fungi was not recognized until the middle 19th century. In 1918, Stoll isolated the first active principle, ergotamine, from ergot.[166] Although ergotamine has some stimulant effects on the uterus, the alkaloid mixture from the sclerotium possesses greater stimulant properties. In 1935, Dudley and Moir isolated the major uterine stimulant, ergometrine (ergonovine) from other ergot alkaloids in the sclerotium.[167]

Ergometrine has a long history of obstetrical use during labor, and the use of ergot alkaloids to reduce postpartum hemorrhage has substantially decreased maternal deaths during labor.[163] Midwives used ergot as an herbal medicine during delivery long before Adam Lonicer recommended the use of three sclerotia (0.5 mg) of ergot for uterine atony in 1582.[168] In 1841, Francis Ramsbotham, founder of the London Obstetrical Society, noted that female midwives used ergot alkaloids as a promoter of labor pains for at least the preceding 150 years despite the recognized toxicity of ergot alkaloids.[169] In the early 19th century, the use of ergot to induce labor was discouraged in Europe because of the increased incidence of uterine rupture, stillbirths, and maternal death.[170] However, the use of ergot to accelerate labor was more widespread in the United States during the early 19th century. By the end of the 19th century, the detrimental effects (e.g., stillbirth) of prolonged, ergot-induced uterine contraction before delivery were widely recognized. In the early 20th century, the prophylactic use of ergotamine for the prevention of postpartum hemorrhage in the United States began. The treatment of migraine headaches with ergot began in the late 19th century in Germany, the United States, and England.[171] Although early medicinal use included the treatment of pruritus, diabetes, hyperthyroidism, and psychosis, as well as a uterine stimulant during labor, the administration of ergot was restricted to the treatment of migraine headaches and postpartum hemorrhage by the 1950s.[172]

PRINCIPAL TOXINS

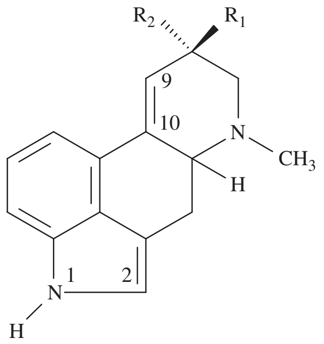
Structure

The term *ergot* applies both to the sclerotium produced by the *Claviceps purpurea* mold and to the ergot alkaloids within the sclerotium. All natural ergot alkaloids (ergolines) are amide derivatives of the tetracyclic compound 6-methylergoline, which is a lysergic acid base chemical structurally similar to a number of biogenic amines (e.g., dopamine, serotonin, norepinephrine). The ergolines in *C. purpurea* primarily are lysergic and isolysergic acid derivatives, whereas ergolines from *C. fusiformis* primarily are derivatives of dimethylergolines (clavines). A previously extracted pharmacologically active compound, ergotoxine, contains four alkaloids (ergocristine, ergocornine, α- and β-ergocryptine). Ergoloid mesylates (dihydroergotoxine) is a mixture of four ergot alkaloids (dihydroergocornine, dihydroergocristine, α- and β-dihydroergocryptine). Figure 45.3 and Figure 45.4 display the chemical structures of ergot amine alkaloids and ergot amino acid alkaloids, respectively.

The majority of the alkaloids can be divided into three groups based on side-chain substitution (see Table 45.6).[173] Ergotamine is the prototype for ergot alkaloids derived from lysergic acid. Reduction of the double bond at the 9-10 position yields dihydroergotamine. In addition, the sclerotium contains several other pharmacologically active substances (e.g., tyrosine, tryptophan, tyramine, histamine, histidine, choline, acetylcholine), but their clinical significance is unclear. Bromocriptine is a synthetic brominated ergopeptide derivative with powerful dopaminergic agonist properties used to suppress postpartum lactation.

Physiochemical Properties

The shape of the sclerotia resembles a rooster's spur, and the term ergot is derived from the old French term for the cock's spur, *argot*. This structure remains the primary commercial source of ergot alkaloids, and these structures typically contain up to 1% ergot alkaloids along with other biologically active alkaloids, amino acids, carbohydrates, lipids, and pigments. The contents of the sclerotia are unique because of the presence of a large triglyceride fraction containing primarily ricinoleic acid. In the absence of other sources of ricinoleic acid (castor oil), the presence of ricinoleate in a foodstuff indicates the presence of *C. purpurea* sclerotia.[337] Hydrolysis of *C. purpurea* alkaloids produces lysergic or isolysergic acid, ammonia, a keto acid, and two amino



Alkaloid	R_1	R_2
d-Lysergic Acid	$-CO_2H$	$-H$
d-Isolysergic Acid	$-H$	$-CO_2H$
d-Lysergic Acid Diethylamide (LSD)	$-C(=O)-N(CH_2CH_3)_2$	$-H$

acids. Lysergic acid derivatives are unstable in light or oxidizing agents, and the decomposition products are inactive. Oxidation products of ergot alkaloids frequently are colored. In solution at equilibrium, about 40% of the ergotamine undergoes isomerization to the relative inactive epimer, ergotaminine.[174]

EXPOSURE

Source

Wind carries fungal spores to the ovaries of young rye. These spores germinate into hyphal filaments that penetrate deeply into rye to form the sclerotia, which are purple-black or purple-red, curvilinear structures that replace the florets of grasses and cereals. The dark, purplish black mass called a *sclerotium* replaces the kernels. The densely packed mycelia represent the body of the mold. The superficial resemblance of sclerotia to kernels permits contaminated rye to enter the human food chain in bread. Exposure to ergot compounds is widespread. All of the leading cereals (barley, oats, rye, sorghum, wheat, corn, millet) are hosts for *C. purpurea* var. *purpurea* (Fr.) Tul., but the first five cereals are the most important hosts. The two important *Claviceps* species involved in human illness are *C. purpurea* and *C. fusiformis* Loveless. *C. fusiformis* is a parasite of pearl millet in Africa and East Asia. Other fungal genera containing ergolines include *Aspergillus* (*A. clavatus* Desm., *A. fumigatus* Fresen.), *Emericella nidulans* (Eidam) Vuill. (*A. nidulans*), *Rhizopus nigricans* Ehrenh., and *Penicillium* (*P. chermesinum* Biourge, *P. concavorugulosum* S. Abe, *P. dierckxii* Biourge). Some higher plants (e.g., *Ipomoea* species) also contain ergot alkaloids.

Environmental Conditions

Warm, rainy spring and summer months favor the sporadic production of ergot alkaloids. The bread baking process reduces, but does not destroy all the ergot alkaloids produced by sclerotia.

Foodstuffs

In general, the main ergolines present in ergot-contaminated cereals, such as wheat and rice are ergocristine, ergocristinine (isomer of ergocristine), and ergotamine.[175,176] Analysis of 14 samples of commercial rye and wheat flour demonstrated the presence of individual ergolines (ergometrine, ergosine, ergotamine, ergocornine, ergocryptine, ergocristine) ranging from 0.3–62 μg/kg.[177] Less common ergolines include ergocryptine, ergocornine, ergometrine, and ergosine. Total ergot alkaloid content for wheat and rye ranged from 0.013–0.307% and 0.011–0.452%, respectively. The total ergot alkaloid content is highly variable from one head to another. The average estimated daily intake of ergot alkaloids from Swiss diets was about 5 μg.[337] Food processing and baking significantly reduces the content of ergot alkaloids.[1] The baking of bread and pancakes using grain contaminated with ergot alkaloids resulted in a 59–100% reduction in the concentration of ergolines in the finished product.[178] The loses of ergot alkaloids in rye and whole wheat bread ranged up to 85% and 100%, respectively.

Medical Uses

Current therapeutic uses of ergot alkaloids include vascular headache prophylaxis and treatment, uterine atonia, senile dementia, orthostatic circulatory disturbances, and infertility secondary to hyperprolactinemia. Ergotamine tartrate is administered for the relief of migraine and related headaches usually in combination with caffeine. Dihydroergotamine (D.H.E.) is an intravenous preparation for the treatment of migraine headaches, but the efficacy of this treatment probably is lower than the use of sumatriptan.[179] The development

of adverse effects following the administration of methysergide limits the usefulness of this drug for the treatment of migraine headaches. Methylergonovine (e.g., methylergometrine) is an effective treatment for postpartum hemorrhage. Dihydroergotoxine mesylate (CAS No. 8067-24-1) is a fixed combination of the following four dihydrogenated ergot alkaloids: dihydroergocornine mesylate (CAS No. 14271-04-6), dihydroergocristine mesylate (CAS No. 24730-10-7), α-dihydroergocryptine mesylate (CAS No. 14271-05-7), and β-dihydroergocryptine mesylate (ergoloid mesylate). Bromocriptine is used to manage amenorrhea, to suppress postpartum lactation, and for the treatment of neuroleptic malignant syndrome.[180] Previous use for hydrogenated ergot alkaloids (ergoloid mesylates) included the treatment of symptoms of idiopathic decline in mental activity of the elderly. Ergonovine was used for the assessment of coronary artery disease.

DOSE RESPONSE

The acute toxic dose of ergot alkaloids varies because of the marked individual susceptibility of patients to the vasoconstrictive properties of ergotamine. Factors that alter the dose response of ergot alkaloids include the presence of vascular disease, hypersensitivity of individual vascular beds, sepsis, smoking, malnutrition, pregnancy, hepatorenal disease, thyrotoxicosis, coronary artery disease, and the concurrent ingestion of certain medications (propranolol, oral contraceptives, xanthine derivatives, erythromycin, ritonavir).[181] Although case reports associated infant fatalities with the accidental ingestion of 12 mg ergotamine[182] and the intramuscular administration of 0.2 mg ergonovine to a newborn infant, the lack of biomarkers and limited laboratory data prevents conclusions regarding causation.[183]

Ergotamine

Substantial variation occurs in the toxicity of ergotamine following a specific dose. The administration of a single rectal suppository of ergotamine by a 32-year-old woman was associated with the development of paresthesias, weakness, difficulty walking, and painful muscle spasms,[184] whereas the chronic ingestion of approximately 4–7 g ergotamine tartrate over 15 years was not associated with any clinical features of ergotism.[185] Atrial fibrillation and precordial pain occurred in a 36-year-old woman after the intramuscular injection of 0.5 mg ergotamine.[186] The abnormalities resolved after 3–4 hours. A case report documented the development of an acute myocardial infarction followed by ventricular fibrillation in a 29-year-old man after the ingestion of 120 mg ergotamine *and* 6 g caffeine.[187] On the second day after admission, peripheral ischemia developed that eventually resolved.

Methylergonovine

The administration of 0.18 mg methylergonovine to a fullterm infant at birth resulted in the development of lethargy, hypercarbia, poor peripheral perfusion, and cyanosis, requiring intubation about 3.5 hours after birth.[188] There was no urine output for the first 16 hours. The infant was treated with nitroprusside infusion (0.3 µg/kg/min beginning 6 hours after birth increasing to 1.2 µg/kg/min) and furosemide. He was extubated at 51 hours after birth and discharged from the hospital after 10 days without obvious sequelae.

Methysergide

This drug is a potent central serotonin antagonist with limited emetic, vasoconstrictive, and uterine constrictive properties. The usual adult dose is 4–8 mg daily. There are few dose-response data on methysergide. A 30-mg adult ingestion resulted in no detrimental effects.[189]

Bromocriptine

Acute toxicity from bromocriptine overdose is relatively mild. An estimated bromocriptine ingestion of 1.5 mg/kg as part of a multiple overdose [Actifed® (Ortho-McNeil, Inc., Raritan, NJ), cyclobenzaprine, cortisone] resulted in a brief period of hallucinations, but there were no sequelae.[190] In an adult, the ingestion of 50 mg bromocriptine produced vomiting, mild hypotension, and sweating, whereas the ingestion of 75 mg caused vomiting in another adult.[191]

TOXICOKINETICS

There are limited data on the toxicokinetics of individual ergolines and ergot alkaloids.

Absorption

The gastrointestinal absorption of most ergot alkaloids with the exception of bromocriptine is relatively low. In addition, the large (>90%), first-pass effect of ergot alkaloids further limits bioavailability following the ingestion of therapeutic doses of ergot alkaloids.[192] Following the intramuscular administration of therapeutic doses of ergotamine, the mean bioavailability was about 47% with a range of 28–61%.[193] Peak plasma concentrations of ergot alkaloids following therapeutic doses occur between 0.5–2 hours after ingestion.[194–196] In a study of volunteers ingesting dihydroergotoxine mesylate tablets, the mean peak concentration of total dihydrogenated ergot compounds was 124 ± 16 pg/mL with

a mean time to peak concentration of 1.15 ± 0.21 hours.[197] Caffeine increases the rate of absorption and the bioavailability of ergot alkaloids.[198]

Distribution

In a study of 10 healthy volunteers, the distribution half-life of ergotamine after intravenous administration was 3 minutes with an approximate volume of distribution of 2 L/kg.[193]

Biotransformation

Biotransformation of ergoloid alkaloids (dihydroergocornine, dihydroergocristine) occurs via oxidation and cleavage of proline in the peptide portion of the molecule as well as by the splitting of the amide bond yielding dihydrolysergic acid amide. A variety of active metabolites that retain the essential ring structures of ergot alkaloids (e.g., 8'-OH-dihydroergotamine) prolong the duration of action of ergot compounds.[192]

Elimination

Elimination of ergot alkaloids occurs almost exclusively by hepatic metabolism and biliary excretion. Mean initial elimination half-lives of most natural ergot alkaloids range from 1.5–6 hours with bromocriptine exhibiting an elimination half-life at the upper end of this range.[194] Following the ingestion of 2 mg ergotamine by health volunteers, the mean elimination half-life was 3.4 hours.[199] Excretion of ergot alkaloids in the bile accounts for approximately 80–90% of the intravenous dose of ergot alkaloid, primarily as metabolites.[194] Urinary elimination of unchanged ergot alkaloids is small (approximately 2%) compared with biliary excretion with most of the ergot metabolites appearing in the bile as conjugated compounds.

Drug Interactions

Propranolol blocks the vasodilating effects of epinephrine and may exacerbate the peripheral vasoconstricting properties of ergot alkaloids.[200] Macrolide antibiotics inhibit the metabolism of ergot alkaloids, potentially causing vasospasm and ischemia.[201] In addition, oral contraceptives and smoking may contribute to vasospasm. Case reports associated coronary vasospasm and cardiac arrest with the administration of ergonovine during coronary catheterization for the evaluation of variant angina.[202] Bromocriptine is a potent dopamine agonist. Case reports associate the therapeutic administration of bromocriptine with aggravation of puerperal mania[203] and affective disorders.[204]

HISTOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The three classes of ergot alkaloids produce different pharmacological effects at therapeutic doses in experimental animals because of their action on a variety of receptors.[173] (See Table 45.7) Both amine alkaloids and amino-acid alkaloids cause uterine contraction, vasoconstriction, and stimulation of the central emetic center. In addition, the latter group (e.g., ergotamine) produces α-adrenergic blockade and vasodilation by inhibition of norepinephrine-induced vasoconstriction.[192] The differences in pharmacological effects between these three groups reflect varying agonist and antagonist actions on several different neuronal receptors including noradrenaline, dopamine, and serotonin (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1F}). Bromocriptine has moderate emetic activity and mild α-adrenergic-blocking properties in experimental animal models.[205]

Mechanism of Toxicity

Ergotamine is the prototype ergot alkaloid compounds, producing peripheral vasoconstriction. Vasospasm results both from central sympatholytic effects and from peripheral adrenergic effects mediated by α-adrenergic and serotonin agonist activity. Although vasospasm potentially occurs in all vessels, symmetrical involvement of the distal arteries is the most common form of

TABLE 45.7. Pharmacological Effects of Selected Ergot Alkaloids

[a]Ergonovine, Methergine, methyl ergonovine.

ergotamine-induced vasospasm. Histological changes of the distal arteries following chronic ingestion of ergot alkaloids include a thickened elastica interna, subintimal and medial fibrosis, intimal lesions, and thrombosis. Occasionally, symptoms may persist despite the absence of pathological changes in the arteries.[206] Decreased sympathetic tone also may produce coronary or mesenteric spasm and bradycardia. Ergotamine directly stimulates the chemoreceptor trigger zone in the medulla oblongata, and nausea and vomiting are the most common adverse effects following the ingestion of therapeutic doses of ergotamine. [195]

Neurological effects of sporadic ergotism are not well documented. Theoretically, focal neuropathies may result from constriction of the nutrient vessels to peripheral nerves or from local arterial vasoconstriction (e.g. monocular blindness resulting from decreased retinal artery perfusion). However, the mechanism of toxicity remains unclear. Bromocriptine is a long-acting dopamine agonist that has central stimulating effects. Potentially, bromocriptine may exacerbate bipolar affective disorders (manic-depressive) or cause hypotension.

CLINICAL RESPONSE

Cases of ergotism result from an acute excessive ingestion, chronic therapeutic use of ergot alkaloids, or the recent ingestion of small amounts of ergot drugs in individuals hypersensitive to them. C. *purpurea* var. *purpurea* (Fr.) Tul. produces ergotamine and ergocristine alkaloids that cause the gangrenous form of ergotism, whereas C. *fusiformis* Loveless produces clavine alkaloids that cause gastroenteritis and a convulsive form of ergotism.[1] Toxicity secondary to ergot alkaloid ingestion is highly variable. Risk factors for the development of ergot toxicity include malnutrition, febrile illnesses including sepsis, coronary artery disease, hepatorenal insufficiency, peripheral vascular disease, smoking, hypertension, pregnancy, and thyrotoxicosis.

Adverse Drug Reactions

Adverse reactions to therapeutic doses of ergot alkaloids include nausea, vomiting, headache, lightheadedness, peripheral vasoconstriction, malaise, muscle spasms, tightness of the throat, and paresthesias. The incidence of vascular spasm after therapeutic doses of ergotamine is small (<0.01%).[207] The administration of therapeutic doses of ergotamine has been associated with vascular insufficiency in the cerebral, mesenteric,[208] renal, [209] ophthalmic,[210] and coronary arteries.[211] Side effects of therapeutic doses of methysergide involve the gastrointestinal (nausea, vomiting, diarrhea) and central nervous (lethargy, anxiety, insomnia, euphoria, confusion) systems. Similar to other ergot alkaloids, the chronic therapeutic use of methysergide has been associated with vascular occlusion at a variety of sites, including the lower and upper extremities, coronary arteries, superior mesenteric arteries, and the aorta.[212,213] Other adverse effects of chronic therapeutic use of methysergide include fibrosis of the heart valves, endocardium, pleura, lungs, great vessels, retroperitoneum, and pericardium.[214]

Acute Ergot Alkaloid Toxicity

Parenteral

Ergot toxicity in the newborn usually results from the inadvertent administration of methylergonovine instead of other medication (naloxone, vitamin K). Accidental parenteral administration of 0.2 mg ergonovine to newborn infants was associated with cutaneous erythema and hemorrhagic blebs on the extremities, groin, and genitalia.[183] The skin lesions appeared on the second day and subsided about the fifth day. The case report did not include any laboratory confirmation of the administration of ergonovine. Following the intramuscular or oral administration of ergometrine, neonates may develop respiratory depression, cyanosis, oliguria, coma, apnea, and seizures.[215,216] Symptoms of intoxication usually develop within 1 hour, but occasionally symptoms are delayed several hours.[188] Death usually results from respiratory failure.

Ingestion

Acute toxicity from the ingestion of ergot alkaloids is rare. Historically, acute (gangrenous) ergotism is associated with a convulsive syndrome that includes hallucinations and delusions as well as vertigo, headache, tinnitus, paresthesias, hyperesthesias, hemiplegia, seizures, muscle spasm, fatigue, and gastrointestinal distress.

Typically, cardiac and gastrointestinal effects begin within 4 hours of ingestion of ergotamine including restlessness, agitation or lethargy, coma, nausea/vomiting, tachycardia, and hypotension;[173] however, manifestations of peripheral ischemia often are delayed until the following day (e.g., cyanosis, cold extremities, paresthesias, pain). A case report associated a large dose of Cafergot® (Novartis, East Hanover, NJ; ergotamine, caffeine) with hemorrhagic gastritis, peripheral cyanosis, cerebral edema, and the death of an infant.[182] Bromocriptine intoxication usually is mild, and clinical features include vomiting, mild hypotension, and diaphoresis.[190] There are few data on the acute toxicity of methysergide. Based on the adverse effects of methysergide, the most likely effects associated with methysergide intoxication include the gastrointestinal and central nervous systems.

Chronic Ergotism

Chronic ergotism typically develops in young, female patients consuming excessive doses of ergotamine for migraine headaches.[217] This chronic, gangrenous form of ergotism usually presents as a symmetrical, bilateral peripheral vascular insufficiency affecting primarily the lower extremities. Common clinical features of chronic ergotism include intermittent claudication, cold extremities, pain, numbness, claudication, cyanosis, paresthesias, pallor, malaise, nausea, vomiting, diarrhea, abdominal pain, and edema. In women, amenorrhea, miscarriages, and poor lactation may occur. In a study of an epidemic of ergotism from the ingestion of food heavily contaminated with *C. purpurea* sclerotia, dry gangrene, reduced peripheral pulses, and desquamation of the skin occurred, particularly in the lower extremities.[218] The most common symptoms were weakness, formication, hyperesthesias, nausea, vomiting, and diarrhea. Less common symptoms included seizure, coma, confusion, diarrhea, syncope, diplopia, blurred vision, psychosis, and bradycardia.[172] Usually, improvement begins within 24 hours of the cessation of ergot alkaloid use, but ischemic symptoms may persist several days.[219] Although peripheral pulses may reappear early, abnormal distal blood flow as documented by angiography may remain several weeks.

Ischemia may occur in the upper extremities,[220] but ischemia is rare in the carotid, coronary, mesenteric, renal, or retinal arteries. Chronic, heavy use of ergotamine (i.e., 6mg/d for 3 months) was associated with portal vein fibrosis and portal hypertension.[221] Cerebral manifestations are uncommon in sporadic ergotism because of the absence of the LSD-like ergot compound, isoergine, in therapeutic preparations. Neurological presentation may be local (e.g., facial palsy) or diffuse (e.g., confusion, hypoalgesias) depending on the affected vascular bed. The differential diagnosis of the peripheral ischemia associated with ergotism includes Buerger's disease, atherosclerosis, vasculitis (collagen vascular diseases), Raynaud's disease, trauma, aneurysms, drug-induced vasospasm (epinephrine, dopamine), arterial dissection, and thromboembolic events.

Symptoms of ergotism from the chronic ingestion of food contaminated with *C. fusiformis* may resemble an acute gastrointestinal illness. Clinical features included nausea, vomiting, and drowsiness within 1–2 hours after ingestion followed by resolution of symptoms within 48 hours.[222] There were no symptoms or signs of vasoocclusive disease. The pearl millet from affected villages contained 15–174g ergot alkaloids/kg with 15–199mg total ergolines/kg in the contaminated grain. The main ergolines were agroclavine, elymoclavine, chanoclavine, penniclavine, and setoclavine. After discontinuation of ergotamine, the course of peripheral ischemia is variable.

Reproduction

The teratogenic potential of ergotamine probably is relatively low.[223] Although some case reports associated high doses of ergotamine with malformation consistent with vascular injury,[224] epidemiological studies have not demonstrated a clear increase in the incidence of malformation among infants exposed to ergotamine *in utero*.[225]

DIAGNOSTIC TESTING

Biomarkers

The effects of ergotism (i.e., ischemia) persist after the concentrations of ergotamines are no longer detectable in the plasma, in part because of tight tissue binding and the production of active metabolites.[192] Consequently, there is no direct correlation between plasma ergotamine concentrations and the clinical features of ergotism.[226] In a study of 25 patients receiving 7–60mg ergotamine tartrate weekly over 1.5–30 years for migraine headache, adverse reactions (cramps, paresthesias, tremor, limb pain) occurred in some of these patients despite the absence of detectable serum concentrations of ergotamine.[227] Although adverse reactions are more frequent when ergotamine concentrations exceed 2ng/mL, these side effects also occur at therapeutic concentrations. During a pharmacokinetic study, adverse reactions developed in 39% of subjects with plasma ergotamine concentrations exceeding 1.8ng/mL, whereas these reactions occurred in about 25% of subjects with plasma ergotamine concentrations below 1.8ng/mL.[195]

Ancillary Tests

Peripheral angiography together with the clinical history and laboratory tests (electrocardiogram, serum cardiac enzymes) help exclude other causes of ischemia (e.g., arterial embolism, arteriosclerosis obliterans, thromboangiitis obliterans, vasculitis, reflex sympathetic dystrophy). Typical angiographic findings in chronic ergotism include generalized, intense arterial spasm, formation of collateral vessels (chronic toxicity), and thromboses.[228] The main feature of the vascular spasm is the smooth, tapered narrowing of the arteries with minimal irregularity of the lumen.[220] The vascular spasm usually involves the medium-sized muscular arteries and small arteries/arterioles rather than large arteries (e.g., aorta, iliac artery).[229] Vascular spasm commonly occurs in the

superficial femoral artery as well as in the external carotid artery with arterial occlusion becoming progressively more severe distally. The absence of atherosclerotic plaques in association with ultrasonographic evidence of occlusive disease suggests the presence of vasculitis or ergotism. The relief of the vasospasm by intraarterial vasodilators in a patient with a history of chronic ergot alkaloid use indicates ergotism.

Abnormalities

Case reports associate mildly elevated serum creatine kinase and alkaline phosphatase concentrations with the ingestion of excessive doses of bromocriptine, but the clinical significance of these changes remains unclear.[165] Ischemic complications of acute ergotamine intoxication include elevated serum concentrations of amylase, lipase, and hepatic aminotransferases.[230]

TREATMENT

Stabilization

Case reports associate cardiac arrest secondary to ventricular dysrhythmias (ventricular fibrillation, asystole) with the therapeutic use of ergotamine during coronary catheterization for vascular disease[202] and following massive acute overdose of ergotamine *and* caffeine.[187] Patients with abnormal vital signs or significant cardiovascular disease should be monitored for cardiac arrhythmias, hypoxemia, and cardiac ischemia. Respiratory depression is uncommon except after the parenteral administration of ergometrine in neonates.[216]

Decontamination

Although there are limited data on the efficacy of decontamination measures for ergot alkaloids, the administration of activated charcoal within 1–2 hours after the ingestion of >0.5 mg ergotamine/kg or >1–1.5 mg methysergide or bromocriptine/kg is a reasonable therapeutic option. Because sensitive individuals may develop vasospasm at therapeutic levels, each patient or parent of the patient should be warned about seeking medical attention if signs or symptoms of vascular insufficiency (cyanosis, pain, paresthesias, mottled coloring, cool extremities) develop, particularly within 24 hours after ingestion.

Elimination Enhancement

There are inadequate pharmacokinetic data to evaluate the effectiveness of measures to enhance the elimination of ergot alkaloids. However, the large apparent volume of distribution and small concentration of ergotamine in the blood indicate that hemodialysis, peritoneal dialysis, diuresis, and hemoperfusion would probably not be effective.

Antidotes

There are no antidotes.

Supplemental Care

Peripheral ischemia

In cases of limb-threatening vascular insufficiency, angiography is an important diagnostic test to determine the etiology of poor peripheral perfusion. Withdrawal of all ergot alkaloids is mandatory. Reduction of precipitating factors (hepatic and renal insufficiency, smoking, febrile illness, thyrotoxicosis, drugs such as oral contraceptives and β-blocking agents) may improve peripheral perfusion. There are few clinical data on the treatment of peripheral ischemia associated with ergotism. Case reports associated the use of intravenous or intraarterial nitroprusside therapy with reversal of severe peripheral ischemia over several days at doses of 2–5 μg/kg/min (0.3–1.2 μg/kg/min in a neonate).[188,231,232] Adjunctive treatment includes the use of oral vasodilators [prazosin (1 mg t.i.d.), captopril (50 mg t.i.d.), nifedipine] for at least several days after the peripheral ischemia resolves. In less severe cases, the use of oral agents may obviate the need for intravenous therapy. Case reports document the use of a variety of therapeutic modalities for refractory cases of ergot-induced vasospasm including sympathetic blockade,[233] surgical sympathectomy, low-molecular-weight dextrans, hyperbaric oxygen, mechanical intraarterial vasodilation,[234] and epidural spinal cord stimulation.[235] However, the use of these modalities remains controversial because of the lack of clinical trials. Heparin and antiplatelet drugs are recommended as prophylactic agents to prevent secondary thrombosis related to stasis.[231] Hospitalization is usually required to monitor the effectiveness of drug therapy.

Coronary Ischemia

Case reports indicate that ergonovine-induced coronary vasospasm during assessment of variant angina pectoris generally responds to sublingual or intravenous nitroglycerin.[202,236] Another case report suggested that the administration of intravenous nitroglycerin at maximum doses of 3.2 μg/kg can reverse peripheral ischemia associated with the use of ergot compounds.[237]

FUMONISIN

HISTORY

Gibberella moniliformis Wineland (*Fusarium verticillioide*) was the predominate fungus isolated from moldy corn involved with an epidemic of equine leukoencephalomalacia in South Africa during 1970. Subsequent studies of this fungus confirmed the pathological changes (i.e., liquefactive necrosis of cerebral white matter) associated with exposure to this fungal species.[238] As a result of investigations into the etiology of equine leukoencephalomalacia, fumonisin B_1 was isolated from *Gibberella moniliformis* Wineland in 1988.[239] During 1989, epidemics of equine leukoencephalomalacia and porcine pulmonary edema in the United States were associated with consumption of feed contaminated with fumonisins.[240]

PRINCIPAL TOXINS

Structure

The basic chemical structure is a C-20 diester of propane-1,2,3-tricarboxylic acid and a pentahydroxyicosane containing a primary amino group. These mycotoxins are long-chain polyhydroxyl alkylamines with two propane tricarboxylic acid moieties esterified to hydroxyls on adjacent carbons. Fumonisin B_1 is the most prevalent of the fumonisin family of mycotoxins that include at least 15 other compounds (e.g., FB_2, FB_3, FB_4, FA_1, and FA_2; see Figure 45.5).[241] Fumonisin B_2 is the C-10 deoxy analogue of fumonisin B_1. FA_1 and FA_2 are the *N*-acetyl derivatives of FB_1 and FB_2, respectively. These fumonisin mycotoxins form through the condensation of the amino acid alanine and an acetate-derived precursor.[242]

Physiochemical Properties

Fumonisin mycotoxins are highly polar, water-soluble compounds with no obvious chromophore in ultraviolet or visible spectrum. Fumonisin B_1 is relatively heat-stable with half-lives 10 minutes at 75 °C (167 °F) and 480 minutes at 150 °C (302 °F).[243] Ethanol fermentation of fumonisin-contaminated corn does not destroy these mycotoxins,[244] and food processing does not significantly alter the concentration of deoxynivalenol in food, even at high temperatures.[245] However, dry milling redistributes the fumonisin compounds into different constituents of maize. Wet milling extracts some of the mycotoxins into the steeping water.[111]

	R_1	R_2	R_3

Fumonisin B_2	H	OH	H
Fumonisin B_3	OH	H	H
Fumonisin A_1	OH	OH	$COCH_3$

FIGURE 45.5. Structure of common fumonisin mycotoxins.

EXPOSURE

Sources

Penicillium and *Aspergillus* species usually contaminate foods during drying and storage, whereas *Fusarium* species are widespread plant pathogens that invade the plant and produce mycotoxins before or immediately after harvest, primarily in maize.[15] Except under extreme conditions, the concentrations of fumonisin do not increase during storage. The main sources of fumonisin mycotoxins are *Gibberella moniliformis* Wineland (*Fusarium verticillioides, Fusarium moniliforme*), and, to a lesser extent, *F. proliferatum* (Matsush.) Nirenberg ex Gerlach & Nirenberg. Other species that produce substantially smaller amounts of mycotoxins include *F. napiforme* Marasas, P.E. Nelson & Rabie, *F. nygamai* L.W. Burgess & Trimboli, and *Alternaria alternata* (Fr.) Keissl.[246] Fumonisin B_1, B_2, and B_3 are the only fumonisin compounds produced in substantial quantities by *Gibberella moniliformis* (*F. verticillioides*) with B_1 being the most significant toxin.[247] The production of FB_1 in strains of *Gibberella moniliformis* is highly variable, and significant accumulation of FB_1 in maize occurs during adverse weather conditions (drought) and insect stress.[248] Fumonisin compounds are uncommon in food products other than maize and maize products; these mycotoxins are infrequent contaminates of rice, beer, sorghum, asparagus, and mung beans.[111,249] Clinically significant concentrations of FB_1 are not present in meat or dairy products from animals fed grain contaminated by fumonisin compounds.[250] These mycotoxins can be produced in liquid cultures.[251]

Environmental Conditions

Fumonisin compounds occur primarily in maize grown under warm, dry conditions, and heat stress is a determinant of the risk of fumonisin contamination of corn.[252] Many *Fusarium* species grow optimally at 24°C–26°C (~75°F–79°F) with a minimum water activity (a_w) of 0.90,[253] and *Gibberella zeae* (Schwein.) Petch (*Fusarium graminearum*, Gibberella ear rot) proliferates optimally under rainy conditions at 26°C–28°C (~79°F–82°F). Minimum growth requirements for *Gibberella moniliformis* include minimum temperature 2°C–5°C (~36°F–41°F, maximum temperature of 32°C–37°C (~90°F–99°F), and minimum water activity of 0.87.[15] Mycotoxin production occurs at water activity ranging from 0.92–0.97.[254]

Foodstuffs

Gibberella moniliformis is a pathogen of cereals (e.g., maize, rice), and fumonisin compounds are common contaminates of corn-based foods including beer.[255,256] Fumonisin B_1 is the most common fumonisin mycotoxin with concentrations up to 250mg/kg in maize.[158] The estimated daily intake of fumonisin B_1 ranges from about 0.02–1.0μg/kg body weight.[111] In a study of Brazilian maize, over 95% of the samples contained fumonisin B_1 at concentrations ranging from 0.6–18.5mg/kg.[257] Mean fumonisin B_1 concentrations were substantially higher in commercial Argentinean samples of corn meal (mean = 0.56mg/kg) than corn flakes (range: 0.02–0.038mg/kg).[258] The median and mean concentrations of fumonisin B_1 in samples of maize from the Netherlands were 420ng/g and 1,359ng/g, respectively.[259] In a study of corn-based human foods in Kansas, about 20% of the samples contained detectable (i.e., >40ppb) concentrations of fumonisins as measured by HPLC with a fluorescent detector.[260] About 50% of the corn flour samples contained detectable amounts of fumonisins at concentrations ranging from 0.765–9.995ppm. Corn syrup and grits are brewing adjuncts in some beer-production processes. In a study of *Gibberella moniliformis* strains isolated from European (Italy, Spain, Poland, France) corn, sorghum, wheat, barley, and mixed feed, the production of fumonisin B_1 in corn cultures ranged from 0.7–4,100μg/g.[261] Fumonisin B_1 and B_2 occur to a limited extent in beer. In a study of 26US commercial beers, 86% of the beer samples contained detectable concentrations of fumonisin B_1 with total fumonisin (B_1, B_2) concentrations in positive samples ranging from 0.3–12.7ng/mL.[262] Treatment of corn-based food products with calcium hydroxide solution substantially reduces the concentrations of fumonisins. Typically, alkali-processed corn foods (tortilla chips, nacho chips, taco shells, corn tortillas) contain <100ng total fumonisins/g.[263] Food processing methods currently used in North America and western Europe do not usually destroy fumonisin B_1.[241] Stability studies indicate that fumonisins are stable in γ-irradiated maize for at least 6 months at 25°C (77°F) and for at least 4 weeks at 40°C (104°F).[264]

DOSE RESPONSE

In rodent studies on male and female Sprague-Dawley rats, the administration of 0, 15, 50, and 150ppm fumonisin B_1 in the feed for 4 weeks was not associated with obvious signs of toxicity (e.g., weight loss, reduced feed consumption).[265] However, microscopic examination revealed renal toxicity (cortical nephrosis) in males fed ≥15ppm and females fed ≥50ppm along with hepatoxicity in males and females fed 150ppm. Liver and kidney samples contained elevated concentrations of sphinganine and the sphinganine/sphingosine ratio.

TOXICOKINETICS

The absorption of fumonisins from the gastrointestinal tract is relatively poor, and the distribution and elimination of these compounds is relatively rapid.[111] These mycotoxins are not metabolized by the cytochrome P450 enzyme system.

HISTOLOGY AND PATHOPHYSIOLOGY

Fumonisin compounds are the first mycotoxins known to inhibit sphingolipid biosynthesis and alter lipid metabolism. In experimental studies, fumonisins competitively inhibit substrates (sphinganine, fatty acyl coenzyme A) of sphinganine *N*-acetyltransferase. The inhibition of ceramide synthase and the disruption of *de novo* sphingolipids synthesis by fumonisin B_1 results in an increase of sphinganine levels and the sphinganine/sphingosine ratio.[266] This enzyme is an important part of the pathway leading to the formation of sphingomyelin and complex sphingolipids. Consequently, fumonisin mycotoxins inhibit cell growth and sphinganine accumulates as a result of the blocking of the synthesis of sphingolipids.[158]

CLINICAL RESPONSE

Animals

The administration of fumonisin to horses produces equine leukoencephalomalacia characterized by necrotic lesions in the brain.[267] Fumonisin B_1 acts as a competi-

tive inhibitor of sphingosine *N*-acetyltransferase, and the resulting blockade of this enzyme causes inhibition of complex sphingolipid biosynthesis and accumulation of sphingosine.[268] Porcine pulmonary edema is another unique mycotoxicoses caused only by the ingestion of fumonisin compounds by swine.[269]

Humans

Despite cases of exposure to maize contaminated with FB_1 concentrations exceeding 100 mg/kg, there are no *confirmed* cases of acute fumonisin toxicity in humans.[241] The consumption of unleavened bread made from fumonisin-contaminated maize and sorghum produced a self-limited gastrointestinal illness characterized by diarrhea and abdominal pain. None of the subjects complained of vomiting. Fumonisin B_1 concentrations in samples of sorghum and maize ranged from 0.14–7.8 mg/kg and 0.25–64.7 mg/kg, respectively.[270] Although guidance levels are available for fumonisins,[271] there is no direct evidence that these mycotoxins produce epidemics of human illness.

Carcinogenicity

There is inadequate evidence of the carcinogenicity of fumonisin B_1 in humans and limited evidence of carcinogenicity in experimental animals. A 2-year study of rodents demonstrated an increased incidence of renal tubule neoplasms in male F344/N rats fed daily fumonisin doses 7.5 mg/kg and of hepatocellular carcinomas in female B6C3F1 mice fed 9.7 mg/kg.[266] The incidence of neoplasms was not increased in female F344/N rats and male B6C3F1 mice fed similar doses. Consequently, the IARC classifies this mycotoxin as possibly carcinogenic in humans (Group 2B). In Chinese provinces with high endemic rates of primary liver cancer, fumonisins frequently contaminate corn-based food along with other aflatoxins and trichothecene compounds.[272] However, the contribution of fumonisins to the increased rates of liver cancer present in these areas is unknown.

DIAGNOSTIC TESTING

Analytical Methods

Chromatographic methods for the detection of fumonisins include economical thin-layer chromatography, liquid chromatographic methods based on solid-phase extraction of solvent extracts, and HPLC using fluorescence detection.[273] Monoclonal and polyclonal antibodies are available to detect fumonisin $B_{1\text{-}3}$.[274,275] Detection limits for fumonisins using HPLC with detection by evaporative light scattering and electrospray detectors were 10–50 ng and <1 ng, respectively.[276] Fluorometric, thin-layer chromatographic and ELISA techniques have limits of quantitation in the range of 0.5–1 μg/g.[151]

Biomarkers

There are no validated biomarkers for human exposure to fumonisins.

TREATMENT

Treatment is supportive.

OCHRATOXINS

HISTORY

In 1965, ochratoxin A was the first mycotoxin isolated from *Aspergillus alutaceus* Berk. & M.A. Curtis.[8] Subsequently, ochratoxins were discovered over a dozen other *Aspergillus* and *Penicillium* species.

PRINCIPAL TOXINS

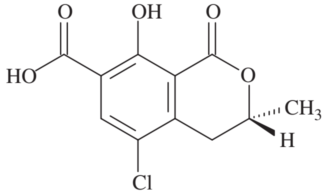
Structure

Ochratoxins are secondary metabolites produced by certain *Penicillium* and *Aspergillus* species that are substituted isocoumarin compounds linked to L-phenylalanine and classified as pentaketides (see Figure 45.6). Ochratoxin α is the only ochratoxin that lacks the phenylalanine moiety. Unlike most other mycotoxins, ochratoxins contain chlorine atoms. Ochratoxin A (CAS No. 303-47-9) is the most abundant and toxic of the five metabolites in the ochratoxin group.[277]

Physiochemical Properties

Ochratoxin A (7-L-β-phenylalanylcarbonyl-5-chloro-8-hydroxy-3,4-dihydro-3-*R*-methylisocoumarin, MW 403.82) is a colorless, crystalline compound with a melting point of about 90 °C (194 °F). This compound is slightly soluble in water, but ochratoxin A is soluble in dilute aqueous sodium bicarbonate and polar compounds. Ochratoxin A is weakly acidic with pK_a values of 4.2–4.4 and 7.0–7.3 for the carboxyl group of the phenylalanine moiety and the phenolic hydroxyl group of the isocoumarin portion, respectively.[277] Under experimental conditions acid hydrolysis of ochratoxin A

	R_1	R_2	R_3
Ochratoxin A	H	H	Cl
Ochratoxin B	H	H	H
(4*R*)-4-Hydroxyochratoxin A	OH	H	Cl
(4*S*)-4-Hydroxyochratoxin A	H	OH	Cl



Ochratoxin α

FIGURE 45.6. Chemical structures of ochratoxins.

yields phenylalanine and the isocoumarin structure called ochratoxin α. The later product also occurs in the intestines of experimental animals fed ochratoxin A-containing feed as a result of microbial degradation.[278] Because ochratoxin A is relatively resistant to food processing techniques, this compound often occurs in cereal and meat or dairy products from animals reared on contaminated feed.[279] However, meats from ruminants do not contain ochratoxin A because the microflora in the gastrointestinal tract metabolizes this compound to ochratoxin α.[280]

EXPOSURE

Sources

Ochratoxin A is a contaminant in cereals, predominately in Europe, that results from the contamination of cereal during storage rather than during plant growth. Over a dozen *Aspergillus* species and *Penicillium verrucosum* Dierckx can produce ochratoxins. The main ochratoxin A-producing species are *Penicillium verrucosum* Dierckx, *Aspergillus ochraceus* G. Wilh., and several related *Aspergillus* species including a few isolates of *Aspergillus niger* var. *niger* Tiegh.[111] Ochratoxin contamination occurs in a wide range of agricultural products (wheat, barley, oats, maize, coffee beans, mixed feed) from Canada, Denmark, Poland, Sweden, Yugoslavia, and the United States.[337] Ochratoxin A and, to a much lesser extent, ochratoxin B are natural contaminants of plant material. The natural habitat of these ochratoxin-producing species is drying or decaying vegetation, seeds, nuts and fruits.

The most common fungi involved in the production of ochratoxin A in cool and temperate regions are *Penicillium verrucosum* Dierckx and *Penicillium nordicum* Dragoni & Marino, whereas *Aspergillus alutaceus* Berk. & M.A. Curtis is the primary producer of ochratoxins in topical and semitropical regions. The fungal species involved with ochratoxin production varies between locations because the growth requirements vary significantly between different ochratoxin-producing species. In a study of western Canadian grains (wheat, barley, oats, rye) using combined morphological and chemotaxonomic methods, the main ochratoxin-producing species were *P. aurantiogriseum* Dierckx and *P. freii* Frisvad & Samson, whereas the most common species in Denmark were *P. verrucosum* Dierckx, *P. aurantiogriseum* Dierckx (*P. cyclopium*), and *P. freii* Frisvad & Samson.[281] Approximately 72% of the isolates were mycotoxin producers in contrast to the typical range of 2–15% of the grain samples.[282] *P. verrucosum* occurs almost exclusively in grain from temperate zones.[19] Cereals from the tropics are unlikely to contain ochratoxin A because *P. verrucosum* Dierckx does not grow well in the tropics.[111] *Penicillium nordicum* Dragoni & Marino contaminates meat products and cheese, whereas *Aspergillus alutaceus* Berk. & M.A. Curtis contaminates a wide variety of foods (e.g., processed meat, smoked or salted fish, dried fruits, spices, beans, dried peanuts).[283] Other ochratoxin producing species include *A. sulphureus* (Fresen.) Thom & Church, *A. sclerotiorum* G.A. Huber, *A. melleus* Yukawa, *A. fonsecaeus* Thom & Raper, *A. niger* var. *niger* Tiegh., and *A. carbonarius* (Bainier) Thom.[158] *A. carbonarius* grows in high temperatures, and this species is a source of ochratoxin A in grapes, dried vine fruits, wine, and coffee.[111] *Penicillium viridicatum* Westling does not produce ochratoxins.[158] In a study of blood samples from the Lebanese Red Cross, about one-third of the samples demonstrated detectable amounts of ochratoxin A with a mean concentration of 0.17 ± 0.01 ng/mL and a range of 0.1–0.87 ng/mL.[284]

Environmental Conditions

Species, humidity, and temperature are important determinants of mycotoxin formation. The two ochratoxin-producing fungal genera differ in the conditions required to grow and produce mycotoxins.[285] The genus *Penicillium* grows well in cold environments, and species from this genus are the major ochratoxin producers in crops grown in colder climates (Scandinavia, Canada).[286] These species grow more slowly than the aflatoxin-producing *Aspergillus* species.[15] Ochratoxin-producing

strains accounted for approximately 28–50% of the *A. alutaceus* Berk. & M.A. Curtis strains isolated from crops grown in warmer climates (e.g., Australia).[287] Under experimental conditions of optimum temperature range of ochratoxin production by *A. alutaceus* was 12°C–37°C (~54°F–99°F) compared with 4°C–31°C (39°F–88°F) for *P. aurantiogriseum* Dierckx (*P. cyclopium*).[288] The minimum water activity values for the formation of ochratoxin in *A. alutaceus and P. aurantiogriseum* were 0.83–0.87, and 0.87–0.90, respectively. The substrate also determines the amount of ochratoxin formed. *P. verrucosum* Dierckx strains produce more ochratoxin on carbohydrate-rich cereals (maize, wheat), whereas *A. alutaceus* produces higher ochratoxin concentrations on oilseeds and protein-rich seeds (groundnuts, soybeans).[289] Although ochratoxin A is stable during refrigeration when stored in ethanol, decomposition of ochratoxin occurs after a few days following exposure to fluorescent light.[290]

Foodstuffs

The main sources of ochratoxin A are cereal and cereal products with the level of contamination typically <200µg/kg.[291] Ochratoxin A is a contaminant of cereals and some beans (cocoa, coffee, soya) in many parts of the world as well as dried fruits, wheat, beer, pork and poultry meats, and nuts.[19] Coffee contains low concentrations of ochratoxin A. In a UK retail survey of 20 samples of roast and ground coffee, the ochratoxin concentration ranged from the limit of detection (0.1µg/kg) to 8µg/kg.[292] Most foodstuffs contain ochratoxin A concentrations below 200µg/kg.[337] A broad survey of over 500 samples of American wheat, barley, green coffee, and roasted coffee indicated that almost all samples contained ochratoxin A concentrations <5ng/g with only four wheat samples and one barley sample above 5ppb.[293] The maximum ochratoxin A concentration (31.1ng/g) occurred in a wheat sample. In a survey of Danish foods, pork contained the highest concentration of ochratoxin A with 81.5% of the samples containing concentrations above the limit of detection (0.02µg/kg).[291] Ochratoxin A rarely occurs in beers due to losses during the mashing step of the brewing process.[125] Ochratoxin B occurs very rarely in foodstuffs, whereas other ochratoxins generally do not occur in surveys of foodstuffs. Protozoan and bacterial enzymes in the forestomachs of ruminants cleave ochratoxin A to ochratoxin α, and therefore ochratoxin is not usually a contaminant of food sources from ruminants.[294] Following the ingestion of ochratoxin-containing feed, ochratoxin A is present in single-stomach animals (e.g., pigs), particularly in the kidney.[295] However, the ochratoxin concentrations are much lower in the liver and muscles.

DOSE RESPONSE

Ochratoxin-induced nephrotoxicity occurs in farm animals at feed concentrations of 200µg/kg. Ochratoxin intake in humans has not been causally related to specific diseases, and the effect of specific ochratoxin concentrations is unclear. The World Health Organization proposed a maximum limit for ochratoxin of 5µg/kg in cereals and 20µg/kg in cereal products.[111]

TOXICOKINETICS

There are few toxicokinetic data on humans. Animal studies suggest that the primary location of ochratoxin A absorption is the duodenum and jejunum, and the kidney is the tissue with the highest concentration of ochratoxin A.[296] The bioavailability of ochratoxin A in animal species ranges from about 40–65%.[297] Ochratoxin A is highly bound (i.e., 99%) to serum proteins, primarily albumin, with little ochratoxin A diffusing into erythrocytes. Biotransformation of ochratoxin A includes cleavage to ochratoxin α and phenylalanine as well as microsomal hydroxylation to nontoxic metabolites, such as 4-hydroxyochratoxin A.[298] Animal studies suggest that renal and, to a much lesser extent, fecal excretion account for most of the elimination of ochratoxin A. Excretion of ochratoxin in breast milk is small.[337] In a study of 111 samples of breast milk from donor mothers in Italy, about 20% (i.e., 22) were positive for ochratoxin A ranging from 0.1–12µg/kg.[299] Limited data on human toxicokinetics indicate that the elimination half-life of ochratoxin A is relative long (i.e., about one month) compared with rodents (1–5 days).[300,301]

HISTOLOGY AND PATHOPHYSIOLOGY

Ochratoxin A competitively inhibits phenylalanine-tRNA synthetase and protein synthesis in bacteria and hepatic cell cultures. The main target of toxicity is the kidney and the proximal renal tubule. In animal studies, ochratoxin A produces kidney damage when fed to ducklings, dogs, chickens, rats, mice, and trout. This mycotoxin is a suspected cause of porcine nephropathy in Denmark based on the replication of similar renal lesions in experimental animals fed subchronic doses (1mg/kg over 3 months) of ochratoxin A.[302]

Mycotoxic porcine nephropathy is a disease of swine kidneys that resembles Balkan endemic nephropathy. Because of the association of porcine nephropathy with ochratoxin A, this mycotoxin is a suspected cause of Balkan endemic nephropathy. However, there are inadequate epidemiological data to confirm a causal

relationship between ochratoxin A with Balkan endemic nephropathy.

CLINICAL RESPONSE

Balkan Endemic Nephropathy

Although the incidence of Balkan endemic nephropathy is declining, this chronic tubulointerstitial kidney disease remains prevalent in rural areas of Serbia, Bosnia, Croatia, Bulgaria, and Romania.[303] This disease affects primarily adults with an age of onset at 30–50 years and a slow progression to end-stage renal failure.[304] There are no unique clinical features of this disease that separates Balkan endemic nephropathy from other causes of renal failure.[305] Clinical features reflect chronic, progressive renal failure with fatigue, anemia, lassitude, headache, weight loss, anorexia, and evidence of renal tubular damage (low-molecular-weight proteins). Table 45.8 lists the clinical characteristics of Balkan endemic nephropathy. Salt retention and hypertension are uncommon features of this disease.

Although sporadic cases of nephropathy occur in areas (e.g., Tunisia) with high ochratoxin content in foods outside the Balkans,[306,307] the disease appears primarily in geographic clusters of rural farming communities with high humidity and high rainfall.[308] Within the geographic distribution of the disease, cases continue to occur in afflicted villages, whereas adjacent villages without a history of Balkan endemic nephropathy remain disease-free. There is a slight predominance of female subjects (1.5:1).[305] Tumors of the urinary tract system frequently occur in patients with Balkan endemic nephropathy, particularly in the renal pelvis and ureters.

TABLE 45.8. Characteristics of Balkan Nephropathy

Characteristic	Features
Epidemiological	Residence in endemic village
	Family history renal disease or urothelial tumors
	Farming
Clinical	Progressive renal insufficiency
	Normochromic anemia
	Polyuria, polydipsia, nocturia, salt loss
	Urothelial tumors
	Abnormalities of urinalysis
	Hypertension (rare)
Physiological	Low-molecular-weight proteinuria
	Impaired concentrating ability and urinary acidification
	Increased uric acid excretion
	Decreased glomerular filtration rate
	Renal insufficiency
Pathophysiological	Focal interstitial edema and sclerosis
	Focal and segmental tubular atrophy
	Hyperplastic intima changes with arteriolar narrowing
	Dilation of renal lymphatics
	Glomerular sclerosis

Source: Adapted from Ref 308.

The exact etiology of this disease is unclear.[309] Because of the striking pathological similarities between ochratoxin A-induced porcine nephropathy and Balkan endemic nephropathy, ochratoxin A is a suspected cause of this disease; however, high concentrations of ochratoxin A occur both in healthy and diseased populations. Circumstantial evidence for a causal link between ochratoxin A and Balkan endemic nephropathy include a higher incidence of deaths from nephropathy during periods that favor fungal growth and a higher frequency of ochratoxin A in foodstuffs from villages with the disease compared with villages without the disease. Although there are inadequate scientific data to establish a causal link between Balkan endemic nephropathy and ochratoxin A, epidemiological studies suggest that the cause is multifactorial [e.g., genetic predisposition, contamination of well water (polycyclic aromatic hydrocarbon), coronavirus, citrinin].[310,311] Alternate etiologies for Balkan endemic nephropathy include the contamination of food sources by seeds of *Aristolochia clematitis*.[312] Seeds of *A. clematitis* (birthwort) contain about 0.65% aristolochic acid, which is associated with the onset of proximal renal tubular necrosis, renal failure, and urothelial cancer following the chronic use of aristolochic acid-containing herbs.[313]

Carcinogenicity

The IARC lists ochratoxin A as a possible human carcinogen (Group 2B) with inadequate evidence in humans and sufficient evidence in experimental animals. Ochratoxin A is carcinogenic to the renal tubular epithelium (renal cell adenomas and carcinomas) in male mice and in rats as well as hepatocellular tumors in mice.[282] *In vitro* studies suggest the ochratoxin A induces renal tumors in animals by a mechanism other than covalent interactions of a reactive metabolite with DNA.[314]

DIAGNOSTIC TESTING

Analytical Procedures

Extraction procedures for ochratoxins typically involve the use of polar solvents (e.g., chloroform) after acidification of the specimen, and identification procedures involve the use of thin-layer chromatogra-

phy with UV irradiation for the visualization of the fluorescent ochratoxin compounds (detection limit near 12 μg/kg).[87] Other detection methods include HPLC (detection limit about 1 μg/kg) and reversed phase HPLC with fluorescence detection,[315] as well as enzyme-linked immunosorbent assay (limit of quantitation about 2.5 μg/kg) and radioimmunoassay for ochratoxin A (detection limit about 0.2 μg/kg).[316] The mean serum to whole blood ratio of ochratoxin A is approximately 1.9–2.0.[317]

Biomarkers

Blood

Ochratoxin A is a ubiquitous mycotoxin occurring in blood samples from residents of countries without a history of Balkan endemic nephropathy. A relatively high percentage of serum samples from these residents contain low concentrations of ochratoxin A. In most European countries, the mean concentration of ochratoxin A in blood samples from the general population does not usually exceed 1 ng/mL.[323] Ochratoxin A was detectable in all plasma samples from 406 Scandinavian blood donors with a mean plasma concentration of approximately 0.2 ng/mL and a 95th percentile of 0.48 ng/mL.[318] The plasma ochratoxin A did not correlate significantly with specific food items (e.g., cereal products, wine, beer pork, coffee, fruit). Using a sensitive HPLC procedure, about 57% of the serum samples from German residents contained detectable concentrations of ochratoxin A with a mean concentration of 0.6 ng/g (range: 0.1–14.4 ng/g).[319] In a study of serum from 368 Swiss subjects, the ochratoxin A concentration ranged from 0.06–6.02 ng/g with medians of 0.24 ng/g and 0.30 ng/g for women and men, respectively, as measured by HPLC with enhanced fluorescence detection.[317] Plasma samples from 144 Canadian residents of 16 different locations contained a mean ochratoxin A concentration of approximately 0.9 ng/mL with a range of 0.29–2.37 ng/mL.[320]

In general, the serum concentrations of ochratoxin A are higher in residents of eastern European countries where endemic nephropathy occurs than in other countries. In a study of Yugoslavia residents, approximately 7% of 639 serum samples from local residents contained ochratoxin A at concentrations ranging from 1–57 ng/g as measured by enzymatic spectrofluorometric procedures.[321] In a study of serum from Bulgarian residents, about 14% of the samples contained detectable concentration of ochratoxin A, and the mean serum concentration was approximately 14 ng/g.[322] However, the mean concentration of ochratoxin A in plasma samples from residents of five Croatian cities was 0.39 ng/mL with substantial variation between different cities.[323] In a nonrandom sample of workers exposed to ochratoxin A in processing of foods (coffee, cocoa beans, spices), the serum ochratoxin A concentrations ranged from 0.94–3.28 ng/mL, whereas ochratoxin A concentrations in air sampled from the breathing zones of these workers ranged from 0.006–0.087 ng/m^3.[324]

Urine

In a study of children from Sierra Leone the urinary concentrations of ochratoxin A ranged from 0.06–148 ng/mL.[157]

Abnormalities

Abnormalities in urine sediment from patients with Balkan endemic nephropathy usually are limited. Proteinuria is mild and intermittent. The proteinuria increases with progressive renal failure. Macroscopic hematuria is uncommon and usually suggests the presence of urothelial tumors. Tubular proteinuria and defects in urinary acidification precede reduction in glomerular filtration rates. Impaired concentration ability is a late manifestation of Balkan endemic nephropathy.

Health Surveillance

The tolerable daily intake (TDI) of ochratoxin A proposed by the Joint FAO/WHO Expert Committee on Food Additives is 16 ng/kg body weight.[325] The basis of this TDI is the lowest adverse effect level in pigs (kidney damage) and a safety factor of 500.

TREATMENT

Currently, federal regulations do not control ochratoxin levels because of the lack of proof that human disease results from ochratoxin consumption. The treatment of Balkan endemic nephropathy is supportive.

PATULIN

Patulin initially was evaluated as an antibiotic (claviformin, clavatin, clavacin, expansine, penicidin) in the early 1940s.[158] *Aspergillus clavatus* Desm. and *Penicillium expansum* Link are the most important patulin-producing species, but several other species of *Penicillium* [*P. griseofulvum* Dierckx, *P. roqueforti* Thom, *P. vulpinum* (Cooke & Massee) Seifert & Samson], *Aspergillus* and *Byssochlamys* also form patulin.[326] *A. clavatus* Desm.

contaminates cereal stubble and malted barley residues, whereas *P. expansum* Link grows on fruits, such as apples and pears. Patulin is relatively unstable, except in aqueous acidic conditions at warm temperatures. This mycotoxin is a lactone. Although the optimum growth temperature for *P. expansum* Link is 25 °C (77 °F), this fungal species can grow at low temperatures (–2 °C/~28 °F).[15] Thermal processing of foods contaminated with patulin causes only a modest reduction in the concentration of patulin.[327] The major source of exposure to patulin for the general population is the consumption of apple juice or other apple products made from contaminated fruits.[328] Occasionally, fruit products with spontaneous brown rot (e.g., cherry, tomatoes, apricots, peaches, pineapples, bananas, grapes) contain low concentrations of patulin. Obvious decay usually occurs in apples contaminated with patulin.[329] Samples of apple juice typically contain patulin concentrations below 50 μg/L (ppb).[330,331] In a study of four Italian apple products, approximately one-third of the samples had detectable concentrations of patulin with the positive samples demonstrating a mean patulin concentration of 26.7 μg/L (range: 1.4-74.2 μg/L).[327] There was no difference in the patulin concentration between products grown under organic and nonorganic conditions. There are few data on the effects of patulin in humans.

Limited human data suggest that patulin rapidly degrades in the human body. In a subject ingesting apple juice containing 50 μg patulin, no patulin was detected in a blood sample drawn 1 hour after ingestion as measured by GC/MS (limit of detection: 200 ng/L).[332] Clinical trials involving the nasal insufflation of patulin did not detect any significant adverse effects.[333] The estimated maximum tolerable daily intake of patulin based on animal studies was 0.4 μg/kg as determined by the Joint Expert Committee on Food Additives of the World Health Organization.[334]

RUBRATOXINS

Penicillium rubrum Sopp is the main fungi associated with the production of rubratoxins, primarily rubratoxin A (CAS RN:22467-31-8, $C_{26}H_{32}O_{11}$) and rubratoxin B (CAS RN:21794-01-4, $C_{26}H_{30}O_{11}$).[166] Moss et al determined the structure of rubratoxin A in 1970.[335] Figure 45.7 and Figure 45.8 display the chemical structures of rubratoxin A and B, respectively. These mycotoxins are present in a variety of animal feed, often in association with *Aspergillus flavus* Link. Rubratoxins cause liver, renal, and central nervous system damage in experimental animals. In a study of rats, the intraperitoneal injection of 0.36 mg rubratoxin B/kg produced hepatoxicity manifest by necrosis of the hepatocytes, disruption of cell membranes, irreversible degenerative changes in cytoplasmic organelles, and intra-sinusoidal hemorrhage.[336] The role of these mycotoxins in human disease is not well defined. Rubratoxins may act synergistically with aflatoxins to produce animal diseases including moldy corn toxicosis.[339]

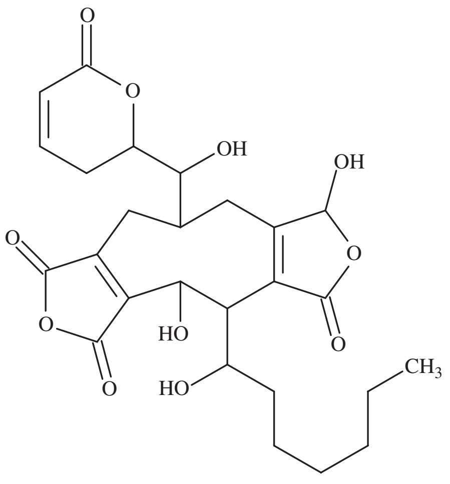


FIGURE 45.7. Chemical structure of rubratoxin A.

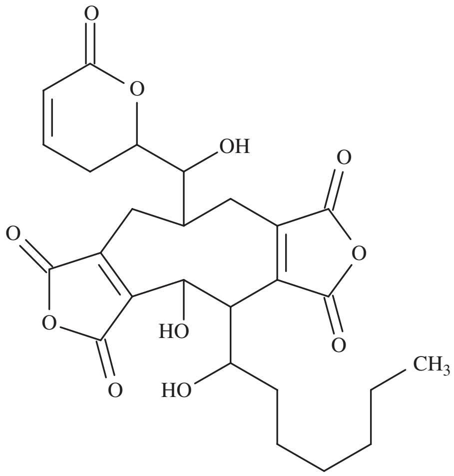

FIGURE 45.8. Chemical structure of rubratoxin B.

TRICHOTHECENES

HISTORY

Trichothecene mycotoxins are a group of over 40 sesquiterpene compounds produced by a variety of widely

distributed fungi.[337] In 1948, Freeman et al isolated the first trichothecene mycotoxin from the mold *Trichothecium roseum* (Pers.) Link.[3] In contrast to the more limited taxonomic distribution of aflatoxins, at least seven genera of fungi contain trichothecene mycotoxins. The trichothecene mycotoxin, T-2 toxin, was a suspected etiological agent for numerous ATA-related fatalities that occurred in Russia during the latter part of World War II.[4]

Stachybotryotoxicosis, a disease in Russian horses that caused pancytopenia and mucosal ulcerations, was the first well-described veterinary mycotoxicosis.[338] The recognition of the importance of clean, uncontaminated straw as a factor in preventing this disease in transport horses by Nikita Khrushchev was an important reason for his early rise to power, in part, because of the importance of these horses to the pre-World War II Russian economy.[339] Trichothecene compounds (i.e., T-2 toxin) were alleged chemical warfare agents in the Vietnam War. The American government described the release of small yellow particles (yellow rain) from low-flying planes on rural civilian populations in Cambodia, Laos, and Afghanistan. Victims reported painful skin lesions, lightheadedness, dyspnea, gastrointestinal irritation, and petechiae followed by leucopenia, anemia, sepsis, and death in susceptible individuals.[340] Survivors allegedly developed a radiation-type sickness that included resolution of bone marrow depression over 3 weeks to 2 months. An autopsy of a suspected victim, who died 31 days after the alleged exposure, revealed interstitial myocardial hemorrhage, acute myocarditis, early micronodular cirrhosis secondary to diffuse hepatic necrosis, and hepatorenal damage.[341] Typical symptoms associated with a yellow rain attack included chills, eye pain, blurred vision, coughing, respiratory distress, vomiting, and blood diarrhea.[342] Although these clinical features are consistent with mycotoxicosis, a causal link to trichothecene mycotoxins could not be established despite the presence of some trichothecene toxins (T-2, DAS, HT-2) in tissue samples from the kidney, liver, and intestine of suspected victims. Human and plant samples of yellow rain taken from contaminated areas by news media reportedly contained three trichothecene mycotoxins (T-2, diacetoxyscirpenol, 4-deoxynivalenol), zearalenone, and the emulsifier polyethylene glycol in a combination that was inconsistent with a natural occurrence.[343,344] In addition, a captured Soviet gas mask allegedly found in Afghanistan was tainted with T-2 mycotoxin.[345] Such findings remain controversial because mycotoxins are ubiquitous, the half-life of T-2 toxin is short, and mycotoxins occur naturally (e.g., honeybee excretions). Scientists from other countries also failed to confirm the presence of mycotoxins in battlefield samples.[346,347]

PRINCIPAL TOXINS

Structure

About 180 trichothecene compounds have been isolated from fungal cultures and plants.[337] Because all these compounds possess a double bond at C9-C10 and an epoxide at C12-C13, they are structurally designated as 12,13-epoxy trichothecenes; all these tetracyclic sesquiterpene compounds contain a 12,l3-epoxy-Δ^9-trichothecene ring system. These naturally occurring toxins are all esters of parent alcohols.[348] There are four main categories based on the presence of specific functional groups (see Figure 45.9 and Figure 45.10). The largest category (type A) lacks a ketone group at C-8 and contains T-2 toxin (CAS No. 21259-20-1) and diacetoxyscirpenol (DAS). Type B trichothecene compounds, an epoxy-sesquiterpenoid, have a carbonyl group at C-8, such as 4-deoxynivalenol (DON, vomitoxin, RD-toxin, deoxynivalenol, CAS No. 51481-10-8) and nivalenol (NIV, CAS No. 23282-20-4). Satratoxin, which contains

Type-A Trichothecenes

a macrocyclic ring system between C-4 and C-5 with two ester bridges, is a type D trichothecene compounds. Only a few of the trichothecenes contaminate food or animal feed. Common trichothecene compounds present in agricultural products include T-2 toxin, 4-deoxynivalenol (DON, vomitoxin), diacetoxyscirpenol (DAS, anguidine), and nivalenol. Less frequent contaminants are 3-Ac-DON, 15-Ac-DON, fusarenon-X and HT-2 toxin. Some type D trichothecenes (satratoxin G and H, verrucarins) occasionally contaminate animal feed (hay, straw),[349] but these macrocyclic trichothecenes are not usually present in food.[337] Stachybocin A, B, and C are spirobenzofuran compounds isolated from *Stachybotrys chartarum* (Ehrenb.) S. Hughes that demonstrate endothelin receptor antagonism.[350]

Physiochemical Properties

Trichothecene mycotoxins are colorless, mostly crystalline compounds that vary in water solubility. These compounds lack native fluorescence and UV absorbance that occurs commonly in aflatoxins. Trichothecene compounds containing an ester group hydrolyze to the corresponding parent alcohol base following treatment with a base. The 12,13-epoxy group is resistant to nucleophilic attack, and trichothecene compounds are generally stable in organic solvents. Mycotoxins produced by *Stachybotrys* are water soluble. Deoxynivalenol and nivalenol are relatively stable, and decomposition of these compounds requires harsh conditions (pH 12, high salt concentration prolonged exposure to 80 °C/176 °F).[351]

Although trichothecene compounds are relatively resistant to acids, sunlight, UV light, x-rays, and temperatures up to 120 °C(248 °F), alkali rapidly degrades these mycotoxins.[101] *In vitro* studies indicate that the actions of coexisting fungi and bacteria in the environment can degrade and detoxify trichothecene compounds.[352]

EXPOSURE

Sources

Stachybotrys

Stachybotrys is a common soil fungus, which is a minor component of indoor and outdoor air throughout the world from temperate climates to deserts.[53] This fungus is not pathogenic, and *Stachybotrys* species prefer stems of woody plants with soil acting as a reservoir.[353] This greenish-black saprophytic mold grows on nonliving, nitrogen-poor material (e.g., wall board) under conditions of high humidity. The fungus can survive over winter and the spores may be viable for many years. Several fungal genera (*Stachybotrys*, *Myrothecium*) produce macrocyclic trichothecene compounds, such as satratoxins, verrucarins, and roridins. *Stachybotrys* species produce >40 different toxins including trichothecenes, spirocyclic drimanes and closely related triprenyl phenolic compounds (e.g., stachybotrylactones, stachybotrylactams).[81] *Stachybotrys chartarum (S. atra)* frequently is associated with the trichothecenes compounds, satratoxin H, and to a lesser extent with satratoxin G. About one-third of *S. chartarum* strains are capable of producing mycotoxins, whereas most strains of *Stachybotrys chartarum* produce spirocyclic compounds.[354] The concentrations of spirocyclic compounds are usually substantially higher than the concentration of macrocyclic trichothecene compounds. Other mycotoxins isolated from *S. chartarum* include satratoxin F, isosatratoxin G and H, roridin E, and verrucarins J and B.[355,356] Roridin E is a precursor of satratoxins. The specific species of *Stachybotrys* are not well defined, and frequently *S. chartarum* (Ehrenb.) S. Hughes is used interchangeably with *S. atra*. Mycotoxin formation rarely is associated with *Stachybotrys* species other than *S. chartarum*.[355] In general, *Stachybotrys* spores are relatively large, and ambient air usually contains few spores even in areas with extensive growth of *Stachybotrys*.[73] In most studies of the general population, *Stachybotrys* has a low prevalence in air samples compared with other fungi (*Penicillium, Aspergillus, Cladosporium, Ulocladium*); and *Stachybotrys* is rarely, if every, found as the predominant species.[101] The prevalence of *Stachybotrys* increases in water-damaged buildings, but most air samples do not contain this mold. In a large US study of air samples collected during indoor air quality investigations, *Stachybotrys chartarum* (Ehrenb.) S. Hughes was identified in indoor air samples from 6% of the buildings and 1% of outdoor air samples surrounding these buildings.[32] The presence of *Stachybotrys chartarum* was not associated health complaints. Of 45 buildings investigated for health complaints, air samples from two buildings contained *Stachybotrys chartarum*. Consequently, *S. chartarum* occurs in air samples from buildings without reports of adverse health effects; therefore, the presence of *S. chartarum* in air samples does not necessarily imply the presence of fungal-related adverse health effects.[357] Animal studies indicate that trichothecene mycotoxins are not volatile because respiratory illness does not occur without the inhalation of spores.[100]

Other Trichothecene Mycotoxins

At least 24 fungal species produce over 40 trichothecene mycotoxins.[15,358] The fungal genera *Gibberella* [e.g., *G. intricans* Wollenw. (*Fusarium equiseti*), *G. zeae* (Schwein.) Petch (*F. graminearum*)] and *Fusarium* (e.g., *F. sporotrichioides* Sherb.) are the most important sources of these tricyclic sesquiterpene compounds because of their prolific mycotoxin production and diverse worldwide habitats. Type A trichothecene compounds (T-2, HT-2) are usually associated with *Gibberella tricincta* El-Gholl, McRitchie, Schoult. & Ridings (*F. tricinctum*), *Fusarium sporotrichioides* Sherb., *Fusarium poae* (Peck) Wollenw., and *Gibberella intricans* Wollenw. (*Fusarium equiseti*), whereas Type B trichothecenes are usually associated with *Gibberella zeae* (Schwein.) Petch (*F. graminearum*) and *F. culmorum* (W.G. Sm.) Sacc. *F. sporotrichioides* Sherb. is the most important source of type A trichothecene compounds. A few plant species (e.g., *Baccharis megapotamica* Sprengel) produce type C trichothecenes. *Gibberella zeae* and *Fusarium culmorum* (W.G. Sm.) Sacc. are plant pathogens that invade certain crops (e.g., *Fusarium* head blight in wheat, *Gibberella* ear rot in maize), and these pathogens produce DON and NIV. Of the numerous trichothecene mycotoxins, four economically important contaminants of agricultural products (wheat, corn, barley) include nivalenol, deoxynivalenol, diacetoxyscirpenol, and T-2 toxin.[345] Diacetoxyscirpenol (anguidine) is the principal mycotoxin in *Gibberella intricans,* and this mycotoxin was used unsuccessfully in preliminary clinical trials as a chemotherapeutic agent.[359]

Environmental Conditions

Stachybotrys

Stachybotrys is a strongly hydrophilic, saprophytic fungi found in moist soil and cellulose-rich substrates (plant

debris, wood pulp, paper, wallboard, cardboard, cotton, straw, hay, grains, cereals) that usually is a minor constituent of indoor air.[360] This fungus produces spores over a wide range of temperatures (<60 °C/140 °F), but the spores seldom appear in outdoor air samples because these spores usually occur in a cluster covered by dried slime. These spores require mechanical stimulation (brushing, washing, renovation, vacuuming) to enter the ambient air, particularly when wet. Although active fungal growth typically requires relative humidity >90%, the water activity of the substrate is a more important determinate of fungal growth.[361,362] The presence of pets, infrequent vacuuming, poor ventilation, and visible mold suggests the presence of high indoor fungal concentrations.[363] However, these factors do not necessarily correlate to high mycotoxin concentrations.

Temperature, nutritional status, and moisture content are the most important determinants of *Stachybotrys* growth. At 25 °C (77 °F), the moisture requirement for growth of *Stachybotrys* is about 93%.[364] Building materials of high cellulose and low nitrogen content (e.g., dust, fiberboard, ceiling tiles, lint, rice paddy grains, sorghum dust, straw) in moist conditions (>55% moisture content) and substantial temperature fluctuations (0–40 °C/32 °F–104 °F) favors the growth of mycotoxin-producing *S. chartarum*.[365] *Stachybotrys* does not compete well with *Aspergillus* and *Penicillium* species, and *S. chartarum* is an uncommon contaminate of indoor air. In a study of Southern California homes, *S. chartarum* was present in <3% of the indoor air samples.[366] Analysis of indoor dust samples for *S. chartarum* confirms the presence of these fungi in the environment, but this type of analysis does not prove that a toxic exposure occurred. Not all strains of *Stachybotrys* produce mycotoxins, and under some environmental conditions some species of *Stachybotrys* lose the ability to produce mycotoxins. Measurement of culturable airborne *Stachybotrys* spores does not necessarily correlate to trichothecene exposure because some nonviable spores may contain high concentrations of mycotoxins. Mycotoxin exposure from *S. chartarum* depends both on environmental conditions and the specific species involved.[355] Furthermore the presence of humid conditions does not imply that mycotoxin-producing *S. chartarum* (*S. atra*) are present. During a study of building-related illness in a water-damaged building, *S. chartarum* was present in only 1 of 19 bulk samples from areas of high moisture content.[367] Furthermore, the presence of *S. chartarum* in bulk samples does not necessarily indicate that satratoxins or verrucarins are present in ambient air at similar concentrations.[35] In a 22-month study of 48 schools with building-related complaints, *S. chartarum* was isolated from swab samples of 11 wet bulk samples.[62] However, no ambient air samples contained detectable concentrations of *S. chartarum*. In a rodent study, few biological effects occurred when the rodents were exposed to vapors from walls completely covered with *S. chartarum*.[100] Measurement of ambient air detected very low concentrations of liberated *S. chartarum* spores. This study suggests that there is no direct correlation between the amount of surface area covered with mold and biological effects.

Other Trichothecene Mycotoxins

Factors that affect trichothecene formation include fungal genetics, substrate, temperature, pH, crop practices, harvesting techniques, and humidity. Acidity apparently does not affect T-2 toxin production in contrast to aflatoxin production. *Gibberella zeae* (*F. graminearum*) is a plant pathogen that produces deoxynivalenol, nivalenol, and zearalenone in an optimum range of 24 °C–26 °C (~75 °F–79 °F) and a minimum water activity of 0.90. When grains are dried to ≤13%, moisture content fungal contamination primarily is a preharvest problem. Storage of grains under moist conditions, as occurs in underdeveloped countries, promotes mycotoxin formation. *F. sporotrichioides* Sherb., which produces T-2 toxin in addition to other trichothecene mycotoxins, has an optimum growth temperature ranging from 22.5–27.5 °C (72.5 °F–81.5 °F) with a minimum temperature of −2 °C (~28 °F).[15] This fungi is the most important source of type A trichothecene compounds, but these mycotoxins do not normally occur in grains during the growing period, harvest, or storage unless water damage develops.

Foodstuffs

DON, NIV, and DAS are more frequent contaminants of food and animal feed than T-2 toxin.[337] DON and NIV frequently contaminate grains (e.g., wheat, rye, barley, oats) at concentrations <1 mg/kg (ppm) and sporadically up to 5–20 ppm.[368] Less often, these mycotoxins occur in rice, sorghum, and triticale. In a survey of 500 cereal grain samples from 19 countries, about 45–50% contained both DON and NIV with barley being the most frequently contaminated grain.[369] Corn and wheat samples contained the highest concentrations of NIV and DON, respectively. There was substantial variation in the presence of these mycotoxins between different countries. Wheat is the major source of DON in most diets with average dietary intake ranging up to about 2.4 μg/kg/d.[111] Although reports document the presence of T-2 toxin in agricultural products at concentrations near 40 mg/kg,[370] analyses of most agricultural products indicate that T-2 toxin is present in detectable concen-

tration in <10% of samples with concentrations usually <0.1 mg/kg.

Most confirmed cases of trichothecene contamination of human food involves DON in wheat or wheat products at concentrations <1 mg/kg.[337] DON can survive the brewing process, and beer occasionally contains DON concentrations exceeding 200 ng/mL.[125] Processing, milling, and baking do not destroy all trichothecene mycotoxins present in foods, although cleaning and milling remove some water-soluble trichothecene compounds. DON fractionates during the dry milling process with the highest concentrations in the bran and the lowest concentrations in the flour.[371] Dry milling reduces the concentrations of DON and NIV up to approximately 40% and 70%, respectively.[372] Processing of flour into baked or cooked products produces variable trichothecene losses. The overall reduction of DON concentrations during the processing of bread from uncleaned wheat ranged from 24–71%.[373] Losses of NIV and T-2 toxin during these processes probably are similar. DON is probably not a significant contaminant of commercial milk or milk products.[374] However, DON survives the beer brewing process and occasionally beer samples contain DON concentrations >200 ng/mL.[125]

DOSE RESPONSE

There are few data on the toxic concentrations of trichothecene compounds, in part, because of the lack of definite evidence to link human toxicity to trichothecene mycotoxins. No cases of alimentary toxic aleukia have been reported since the end of World War II probably because of improved agricultural and storage practices. Acute LD_{50} animal data provide the best available comparison of trichothecene mycotoxin toxicity, but significant variation between species limits extrapolation to humans.[87] Consumption of grains containing 0.02–3.5 mg DON/kg probably does not cause adverse effects.[111] The established limits for DON range between 0.5 ppm and 2 ppm.[375] In an early-phase clinical trial involving the administration of intravenous diacetoxyscirpenol (Anguidine) to patients with advanced malignancies, no biological effects were observed at daily doses of <2.4 mg/m^2 for 5 consecutive days.[376]

The toxicity of *S. chartarum* spores is highly variable (i.e., >10,000-fold) depending on the amount of satratoxins G and H, verrucarin J, roridin E, stachybotrylactones, and stachybotrylactams contained within the spores.[377] Following the intranasal installation of 10^5 toxic *S. chartarum* spores to rodents, there was histological evidence of definite pulmonary inflammation, but there was no evidence of necrosis. The intranasal instillation of 10^5 relatively nontoxic *S. chartarum* spores caused mild pulmonary inflammation.[378] The intranasal instillation of 10^3 of the less toxic spores produced no pathological evidence of pulmonary damage. Although pathological changes occurred in the lungs of the mice exposed to the toxic spores, the exposed mice did not demonstrate clinical changes or significant differences in weight gain when compared with nonexposed controls. During an experimental study, mice were exposed to a chamber that contained a *S. chartarum* load (i.e., surface area covered with mold per m^3 of air) several times greater than a normal room containing mold on all walls, floor, and ceiling.[100] Sensory irritation, bronchoconstriction and pulmonary irritation did not develop despite the presence of airflow 4 times greater than normal ventilation rates. The lack of clinical effects was consistent with the low concentration of volatile organic compounds emitted from the *S. chartarum*. These studies suggest that the concentrations of airborne spores of *S. chartarum* realistically attainable in indoor air are too low to produce clinical effects.

TOXICOKINETICS

There are limited data on the toxicokinetics of trichothecene compounds with most animal studies involving T-2 toxin and, to a lesser extent, DON. Extrapolation of animal data to humans is limited by substantial intraspecies variation in the response to trichothecene compounds. In general, these studies indicate that the absorption of these compounds from the gastrointestinal tract is rapid.[337] However, the bioavailability of trichothecene compounds is relatively low because of the physiological instability of these compounds and large first-pass metabolism.[379] *In vitro* studies suggest that absorption of trichothecene mycotoxins may occur through the skin with some variability between individual mycotoxins (e.g., DAS and T-2 toxin > verrucarin A).[380] However, the risk of systemic toxicity following dermal application of these mycotoxins is unclear because several of these studies utilized dimethylsulfoxide to enhance dermal absorption. Some metabolism of these mycotoxins occurs in the skin prior to systemic distribution. The distribution of trichothecene mycotoxins within the body is relatively even without accumulation in specific organs. Biotransformation of trichothecene mycotoxins to nontoxic metabolites involves hydrolysis, hydroxylation, de-epoxidation, and conjugation with glucuronides. Animal studies indicate that there is substantial variation in metabolic pathways between species. In a study of dogs, the elimination half-life T-2 toxin and its metabolite, HT-2 toxin, administered intravenously was about 5 minutes and 20 minutes, respectively.[381] Although there is substantial variation in the metabolism of DON, all animal species metabolize DON and bioaccumulation of DON does not occur.[375] In sheep,

DON was eliminated within 20–30 hours.[382] Animal studies indicate that <1% of T-2 toxin and DON administered to chickens and cows appears in eggs and in milk.[374,383]

HISTOLOGY AND PATHOPHYSIOLOGY

When administered chronically to animals, trichothecene compounds produce a wide variety of pathological responses including cutaneous inflammation and necrosis, mucous membrane lesions, gastrointestinal inflammation and hemorrhages, petechiae, ecchymosis, and hematological and immunological suppression (e.g., granulocytopenia, anemia). The relative systemic toxicity of trichothecene compounds in order of most potent to least potent are T-2 toxin, diacetoxyscirpenol (DAS or anguidine), NIV, and deoxynivalenol (DON or vomitoxin). Trichothecene compounds bind to the 60S ribosomal subunit and inhibits the enzyme peptidyltransferase. Deoxynivalenol (DON) is an exception because exposure to DON at low doses causes upregulation of protein synthesis as well as polyclonal immunoglobulin production.[384] The resulting interactions cause various degrees of disruption of the formation of peptide bonds. Sites of action of these compounds include the initiation of protein synthesis (T-2 toxin, DAS, scirpentriol, 15-acetoxyscripendiol, verrucarin A) and elongation or termination of protein synthesis (trichothecin, verrucarol).[101] In animal studies, T-2 toxin and DAS produce necrosis of epithelial tissue, cytotoxicity of rapidly proliferating tissue (e.g., intestinal crypt epithelium, hematological tissue), and coagulation defects.[385] In rodents, skin irritation occurs about 6 hours after the dermal application of <1 μg/cm^2 T-2 toxin and verrucarin A.[386] Diacetoxyscirpenol (DAS) and nivalenol (NIV) are less potent skin irritants compared with T-2 toxin and verrucarin A. *Stachybotrys* species also produce spirolactones and spirolactams that demonstrate endothelin receptor antagonism, immunosuppression, and anticomplement activity.[101,356]

Severe toxicity of T-2 toxin and DAS cause suppression of cell-mediated and humoral immunity, reduced immunoglobulin formation, depressed phagocytic activity, and pancytopenia.[387] Alteration of immune parameters decreases resistance to secondary infection of bacteria, yeast, and viruses. In studies of cats, the administration of T-2 toxin in feed caused a clinical syndrome similar to ATA.[388] Removal of this toxin from the *Fusarium* culture fed to the cats resulted in healthy animals.

Trichothecenes are potent inhibitors of protein synthesis and these compounds are particularly active at the peptidyl transferase center on the 60S ribosomal subunit. Experimental work suggests that some trichothecene mycotoxins interfere with chain termination by blocking the interaction between peptidyltransferase and releasing factor on the ribosome.[389] Experimental animal studies also suggest that satratoxins are more potent pulmonary toxins than spirolactones and spirolactams based on the amount of pulmonary inflammation following intranasal instillation.[390]

CLINICAL RESPONSE

Food-Related Illnesses

The main route of exposure to trichothecene mycotoxins is the ingestion of plant material contaminated with mycotoxins. Other theoretical sources of exposure include accidental dermal contact during laboratory procedures and inhalation of dust containing trichothecene mycotoxins. Although several case reports associate the outbreak of food-related illness with trichothecene exposure, there are no epidemiological studies documenting illness in patients with elevated trichothecene concentrations. An outbreak of an acute gastrointestinal illness in China was associated with the consumption of moldy cereals. The latency period was short (5–30 minutes) and symptoms included nausea, vomiting, diarrhea, abdominal pain, lightheadedness, and headache. The most prominent symptom was vomiting. There were no fatalities. Analysis of the moldy cereal from samples stored 6–8 years revealed high concentrations (up to 50 mg/kg) of DON as well as lower concentrations of NIV and other mycotoxins (zearalenone, fumonisin).[391] A similar outbreak of food poisoning occurred in India after the consumption of bread produced from flour contaminated with mycotoxins (DON, NIV Ac-DON, T-2 toxin).[10] The reported symptoms, which began within 1 hour after ingestion of the bread, in order of most frequent to least frequent, were abdominal pain, throat irritation, diarrhea, bloody stools, and vomiting. There were no fatalities. Trichothecene compounds are not recognized carcinogens based on limited data. Although T-2 toxin and DON cause immunosuppression in animal models, there are no clinical data that document the immunosuppression, opportunistic infections, or cancer in subjects exposed to trichothecenes.[337] The International Agency for Research on Cancer lists DON, NIV, and T-2 toxin as agents not classifiable as to their carcinogenicity (Group 3).[392]

Alimentary Toxic Aleukia

Although there is a lack of confirmatory scientific evidence to confirm Koch's postulates for establishing

causation, strong circumstantial evidence associated the ingestion of moldy grain containing *Fusarium poae* (Peck) Wollenw. and *Fusarium sporotrichioides* Sherb. with fatal epidemics of alimentary toxic aleukia (ATA) occurring in Russia between 1931 and 1947. These grains remained in the fields during severe winter conditions as a result of war. The associated *Fusarium* species are capable of producing mycotoxins, such as T-2 toxin, HT-2, and neosolaniol. Multifactorial causes probably are involved in the occurrence of ATA because no similar outbreaks have occurred since the late 1940s. Clinical features of this illness were similar to radiation toxicity and to equine stachybotryotoxicosis with prominent features including necrotic lesions of the upper gastrointestinal tract (oral cavity, esophagus, and stomach), bone marrow hypoplasia, and leukopenia. Symptoms included fever, nausea, vomiting, diarrhea, leukopenia, bleeding, and sepsis. *Stachybotrys* species have not been implicated as a cause of ATA, and humans exposed to aerosolized mold during outbreaks of equine stachybotryotoxicosis developed dermal rather than systemic complaints.[101]

Clinically, ATA is divided into four stages (see Table 45.9).[393] Typically, stage 1 involves the delayed onset of gastrointestinal symptoms along with fatigue, weakness, and sore throat. During the latent period, fatigue and weakness may persist as increasing suppression of the bone marrow develops. About 3–4 weeks after exposure, clinical evidence of coagulopathy and granulocytopenia appear. Increased susceptibility to infection complicates the clinical picture. Death typically occurs during stage 3. Improving bone marrow function characterized by increasing white blood cell counts is a sign of recovery (stage 4). Permanent sequelae did not usually occur in surviving patients. Presently, the exact etiology of this disease remains unknown including the contribution of starvation, poor living conditions, and inadequate medical care.

Scaby Grain Toxicosis

Scaby grain toxicosis is a gastrointestinal disease associated with the consumption of *Fusarium*-contaminated food in Japan and Korea between 1946 and 1963.[394] Clinical features include nausea, vomiting, diarrhea, and abdominal pain that resolved over several days. There were no fatalities. The exact etiology of this disease has not been identified, but a trichothecene mycotoxin is a possible etiological agent.

Diacetoxyscirpenol

Diacetoxyscirpenol (anguidine) underwent unsuccessful clinical trials as a chemotherapeutic agent at 5-day/week intravenous doses of $5\,mg/m^2$ for 3 weeks.[359] Side effects recorded during these clinical trials included nausea, vomiting, diarrhea, hypotension, fever, chills, mucosal ulcerations, cutaneous erythema, hair loss, and bone marrow suppression. There were inadequate data to separate adverse reactions from treatment with anguidine and symptoms related to the progression of metastatic cancer. Some episodes of hypotension were severe enough to require termination of chemotherapy.[395] Dose-related myelosuppression was the limiting adverse effect following prolonged infusion.[396]

Stachybotrys Mycotoxicoses

Mycotoxicoses involving trichothecene mycotoxins usually result from the ingestion of mold-contaminated food or animal feed. The studies associating airborne exposure to *Stachybotrys* with primarily dermal toxicity are mainly descriptive, and there are no well-designed epidemiological data to confirm the association of airborne exposure to *Stachybotrys*-produced mycotoxin with human toxicity.[397,398] The lack of a simple, reliable biomarker of *Stachybotrys* exposure and of objective medical data on abnormalities in patients with *Stachybotrys* exposure limits conclusions regarding the causal link between these mycotoxins and human toxicity. Typically, sites contaminated with *Stachybotrys* also contain many other fungal species (e.g., *Penicillium, Alternaria, Aspergillus, Cladosporium*). The potential presence of irritancy, allergic reactions (dust mites), and infections (gram-negative bacteria, endotoxins, mycobacteria) in damp environments complicate the interpretation of *Stachybotrys* studies that do not exclude health effects associated with damp environments. For example,

TABLE 45.9. Clinical Stages of Alimentary Toxic Aleukia

Stage	Onset[a]	Phase	Symptoms
1	3–9	Gastrointestinal	Salivation, sore throat, headache, lightheadedness, weakness, fatigue, abdominal pain
2	10–14	Latent	Improved symptoms, increasing clotting abnormalities, bone marrow hypoplasia (thrombocytopenia, anemia, granulocytopenia)
3	21–28	Hematological	Bleeding gums, epistaxis, GI hemorrhage, secondary infection, sepsis, death
4		Recovery	Improved bone marrow function

[a]Days after initial exposure.

illnesses associated with damp environments that contain fungi include allergic rhinitis, asthma, hypersensitivity pneumonitis, Legionnaire's disease, and humidifier fever. The proliferation of mold and the chemical degradation of building materials (e.g., emission of 2-ethyl-1-hexanol from alkaline degradation of diethylhexyl phthalate) cause nasal inflammation in occupants of damp buildings.[399] The presence of excessive fungal growth also suggests the presence of inadequate building design and maintenance. Furthermore, the presence of mycotoxin-producing fungi does not necessarily imply exposure to a mycotoxin. Although there are case reports that include nonspecific, subjective complaints involving the neurological and immune systems, there is no conclusive data that links airborne exposure to *Stachybotrys* with neurological or immune damage.[101,109]

Stachybotryotoxicosis

Stachybotryotoxicosis is a disease described in Russian horses, which ate moldy hay contaminated with *Stachybotrys*. To date, this disease has not been reported in animals from North America.[400] The presentation of stachybotryotoxicosis is similar to alimentary toxic aleukia, but ATA is associated with *Fusarium* rather than *Stachybotrys* species.[166,401] Although some investigators associated human illnesses with exposure to *Stachybotrys*, reports from Russian investigators lacked reliable epidemiological data confirming the presence of this disease in humans.

Pulmonary Hemorrhage

A clinical series of 30 infants in Cleveland suggested the possibility of an association between acute pulmonary hemorrhage and water-damaged homes that contained *S. chartarum* among other potential causes (environmental tobacco smoke, sepsis with acute respiratory distress syndrome, general anesthesia).[402] A case-control study of 10 cases of pulmonary hemorrhage and hemosiderosis among infants demonstrated the presence of a high incidence of water damage, family members with hemoptysis, and exposure to environmental smoke in the cases compared with controls.[403] The statistically significant association between pulmonary hemorrhage and the presence of *S. chartarum* was relatively weak (OR = 1.6) compared with other environmental factors (e.g., smoking, OR = 7.9). There was no objective evaluation of the water damage or measurements of the actual exposure to airborne mycotoxins. Aggressive air sampling after the return of the infants demonstrated the presence of *Stachybotrys* in the homes of 5 of 9 patients at a mean concentration of 43 colony-forming units (CFU)/m^3 and in 4 or 27 control homes at a mean concentration of 4 CFU/m^3.[404] However, the use of aggressive sampling techniques that agitate ambient air prevents the quantitative evaluation of the actual exposure to trichothecene compounds in these homes. *S. chartarum* was detected in surface samples from 4 of 7 case homes and 10 of 19 control homes; therefore, the presence of the *S. chartarum* spores in surface samples does not imply the development of pulmonary hemorrhage. In addition, air sampling from some Cleveland and most Chicago homes of infants with pulmonary hemorrhage did not detect spores of *S. chartarum*.

Analysis of isolates from these *S. chartarum* spores revealed the presence of satratoxin H in 3 of 16 isolates along with trichoverroid trichothecene mycotoxins (roridin L-2, trichoverrol B).[405] Some of the isolates from control homes also contained satratoxins and trichoverroid trichothecenes including strains that produced the highest concentrations of trichothecene compounds. Comparison of *S. chartarum* strains from case homes and control homes did not demonstrate significant differences in the potency of the mycotoxins formed.[406] The frequency of highly toxic strains of *S. chartarum* from Cleveland was about the same as the frequency of similar strains from samples outside Cleveland, although three of the *S. chartarum* strains isolated from homes with pulmonary hemorrhage were both very highly toxic and hemolytic.

A subsequent review by a panel of outside experts and a panel of senior scientists organized by the Centers for Disease Control and Prevention (CDC) concluded that the association between acute pulmonary hemorrhage/hemosiderosis (AIPH) in infants and exposure to molds, specifically *Stachybotrys chartarum* was not proven.[407] The panels noted that serious shortcomings in the collection, analysis, and reporting of data resulted in inflated measures or association between *S. chartarum* and AIPH, resulting in a reduction in the OR from 9.8 to 1.5. Furthermore, the panels indicated that AIPH is not consistent with previous clinical effects associated with *S. chartarum* and that similar illnesses have not been reported in other flood-prone areas, which favor the growth of *S. chartarum*. The low spore counts and low trichothecene toxicity of the air samples in homes of infants developing pulmonary hemorrhage suggests the presence of multiple etiological factors (e.g., tobacco smoke, lack of breast feeding) in addition to the presence of *S. chartarum*.[408] The original cluster of cases occurred in a relatively small geographic area near Cleveland, Ohio. However, idiopathic pulmonary hemorrhage occurs in infants sporadically across the United States and the association of *S. chartarum* with these cases is unclear. Investigation of the home of a 40-day-old infant who developed idiopathic pulmonary hemor-

rhage in Florida, did not demonstrate the presence of *S. chartarum*.[409] A case report from Houston suggested that idiopathic pulmonary hemorrhage in infants might be associated with an invasive, hemolytic strain of *S. chartarum* rather than a mycotoxin.[410]

Building-Related Illness

The presence of excessive fungal growth in a building indicates inadequate building design, construction, and/or maintenance. Although some observational studies implicate mycotoxin-producing fungi (*Aspergillus, Penicillium, Stachybotrys*) as possible etiological factors of building-related illnesses, there is no clear evidence at the present time that mycotoxins contribute significantly to the symptoms associated with mold-contaminated buildings or with building-related illnesses.[73,101,411,412] Most homes of occupants with complaints related to building-related illness do not contain detectable concentrations of *Stachybotrys* in air samples.[367,413] A case report documented the presence of nonspecific symptoms (upper respiratory tract symptoms, sore throat, diarrhea, headache, dermatitis, focal alopecia, malaise) in occupants of a residence containing insulation and heating ducts heavily contaminated with *Stachybotrys chartarum*. Analysis of a sample of ceiling fiberboard contaminated with *S. chartarum* spores demonstrated the presence of macrocyclic trichothecenes (verrucarin B and J, satratoxin H, trichoverrins A and B). There was no sampling of ambient air to confirm the presence of airborne *S. chartarum* spores. Laboratory and physical examination of these patients did not detect any abnormalities. There is no substantive evidence that neurological injury including encephalopathy results from the inhalation of mycotoxins from the indoor environment.[14]

A case-control of 53 employees (female to male ratio = 2.8:1.0) and 21 controls (female to male ratio = 1:1) examined differences in 187 self-reported symptoms and a test battery of nonspecific serum tests (complete blood count, flow cytometry, lymphocyte function tests, natural killer cell activity).[414] There was no environmental data on the presence of *S. chartarum* in the work environment of controls. Reporting and selection bias are potential complications of the interpretation of this study because the cases presented to an occupational clinic for evaluation of potential workmen's compensation claims as a result of employment in building contaminated with a variety of fungi including *Stachybotrys*. There were statistically significant differences in the presence of symptoms related to the following areas: lower respiratory tract, skin, eye, and constitution. The study did not report any medical evaluations of the subjects enrolled in the study. However, there was no correlation between objective tests of respiratory and immune function and quantitative measures of mycotoxin exposure. There were some statistically significant differences in the white blood cell count, proportion of mature T-cell lymphocytes (CD3) and natural killer cell counts between workers in different locations. However, the differences were small and not dose-related. The subjects working in the basements, which contained the highest fungal concentrations, had elevated white blood cell counts and percentages compared with workers in other parts of the building. Although *Stachybotrys* was present in the buildings, no *in vitro* or *in vivo* assays confirmed that mycotoxins were present in ambient air. There is no convincing evidence that significant immunological suppression or modulation results from the inhalation of mycotoxins in the indoor setting.[14]

Several studies report an increased prevalence of chronic fatigue and respiratory symptoms in occupants of buildings containing fungi including *Stachybotrys*. These studies have not identified clinically significant immune dysfunction, antibodies directed against *S. chartarum*, or respiratory dysfunction. In general, these observational studies do not control important host and environmental confounding factors. A cross-sectional study of 197 occupants of a building with moisture-damaged interior demonstrated an excess number of respiratory symptoms (cough, dyspnea, feverishness, wheezing, and chest tightness when compared with controls from a building selected for convenience rather than confounding variables (e.g., smoking, asthma, atopy, mold allergies, job dissatisfaction, environmental contaminates).[415] Medical examinations of selected occupants detected asthma and reduced carbon monoxide diffusing capacity in a few cases, but there was no direct correlation between respiratory symptoms and decrements in pulmonary function (e.g., FEV_1, FVC). Ceiling tiles from one of three rooms tested in the contaminated building contained *S. chartarum* spores that produced satratoxins, but there were no direct measures of exposure to these mycotoxins. In this study, exposed occupants and matched controls did not have statistically significant differences in serum antibodies to fungi; consequently, there was no objective evidence that the occupants were exposed to clinical significant quantities of mycotoxins. Fungal cultures revealed other mycotoxin-producing organisms (*A. versicolor*) in addition to *S. chartarum*.

Carcinogenesis

The evidence for carcinogenicity following exposure to T-2 toxin is weak.[111] This mycotoxin is classified as IARC Group 3 (not classifiable with regard to carcinogenicity to humans). In general, studies of genotoxicity following

T-2 exposure are negative. Currently, there is no evidence that exposure to trichothecene mycotoxins (e.g., satratoxins) produces cancer in humans.[337]

DIAGNOSTIC TESTING

The complex physical and chemical properties of trichothecene compounds preclude the use of simple extraction and identification methods. Analytical methods include thin-layer chromatography, gas chromatography (GC), gas chromatography/mass spectrometry (GC/MS) with derivatization, high performance liquid chromatography (HPLC), and immunological techniques. Detection limits usually are <1 µg/g. Gas-liquid chromatography sensitivity for T-2 toxin is 0.03–0.05 ng/L (ppb); GC/MS is slightly more sensitive (0.02 ng/L). Sensitivity for trichothecenes analyzed by gas chromatography-negative chemical ionization tandem mass spectrometry with derivatization by heptafluorobutyryl esters was 1 ng/g.[416] The T-2 metabolite, T-2 tetraol, is stable in urine stored at −70 °C (−94 °F) for 6 months.[417] In blood samples stored at 4 °C (~39 °F), T-2 and HT-2 degrade substantially over 1 month. The limit of quantitation of deoxynivalenol using gas chromatographic methods and Florisil SPE cleanup is approximately 10 ng/g compared with 200 ng/g for thin-layer chromatographic techniques.[151] The mean deoxynivalenol concentrations in urine samples from a small, nonrandom sample of Chinese residents from suspected areas of high and low exposure to deoxynivalenol were 37 ng/mL (range: 14–94 ng/mL) and 12 ng/mL (range: 4–18 ng/mL), respectively.[418]

Classic bioassays for trichothecene compounds involve the skin necrosis test in rodents, rabbits, or guinea pigs based on the development of erythema, edema, intradermal hemorrhage, and necrosis. This test detects T-2 mycotoxins in the range of 0.2 µg.[419] Radioimmunoassay can detect T-2 in the range of 1–20 ng with minimal cross-reaction to other mycotoxins.[420]

Presently, there is no reliable commercial biomarker of acute or chronic exposure to trichothecene mycotoxins including satratoxins. Enzyme immunoassays demonstrate the presence of IgG and IgE antibodies against *S. chartarum*. In a study of 132 samples of sera from blood donors in Missouri, immunoblot analysis detected IgG and IgE antibodies in about 49% and 9% of the samples, respectively.[421] Because of the potential of cross-reaction with other fungal proteins, the presence of these antibodies does not confirm exposure to *S. chartarum*. In general, antigen-specific IgA concentrations are not useful adjuncts for the evaluation of allergic reactions. The results of commercial fungal immunological assays must be interpreted cautiously and correlated to the clinical presentation because current fungal allergen extracts lack standardization and specificity.[422] For example, some *S. chartarum* antigens cross-react with common fungi (e.g., *Aspergillus fumigatus, Alternaria alternata*).[423] Therefore, the presence of antibodies cross-reacting with *S. chartarum* antigen does not necessarily imply exposure to this fungus or to mycotoxins. Case reports of respiratory illness have not correlated *S. chartarum* antigens to clinical symptoms.[415] Alternatively, enzyme-linked immunosorbent assay methods have been developed for the detection of stachylysin in serum as a biomarker of exposure to *S. chartarum*.[424] However, there are inadequate data on the specificity and sensitivity of this potential biomarker to quantify the dose-exposure relationship between this assay and the amount of exposure to *S. chartarum*.

TREATMENT

There are little data on the treatment of trichothecene toxicity. Generally, the treatment of trichothecene exposure is supportive. Activated charcoal binds T-2 toxin in experimental models. The simultaneous administration of super-activated charcoal and T-2 toxin prevents the development of T-2 toxicosis in these animals.[425] Consequently, the use of activated charcoal as a decontamination measure for the ingestion of trichothecene compounds is a reasonable treatment when administered within 1–2 hours of ingestion. In animal models, polyethylene glycol 300 is a more effective dermal decontamination agent than aqueous soap solution.[386] Simple cleaning methods involving removal of damaged material and spraying affected areas with bleach usually control fungal contamination. The most important actions involved with the remediation of homes containing mold include the following: maintenance of heating, ventilation, and air conditioning; inspection and repair of water damage; regular cleaning of the home with dust removal and carpet cleaning; and the removal of visible mold. Sodium hypochlorite (i.e., one cup common bleach per gallon water applied for 15 minutes) degrades trichothecene compounds, but the toxicity of the breakdown products is unknown.[426] The presence of *Stachybotrys* requires no special precautions other than the usual methods for the elimination of mold problems.

ZEARALENONE

Zearalenone (F-2 toxin) is a phenolic resorcylic acid lactone derived from several *Fusarium* and *Gibberella* species including *F. crookwellense* L.W. Burgess, P.E.

Nelson & Toussoun, *F. culmorum* (W.G. Sm.) Sacc., *F. oxysporum* Schltdl., *F. sporotrichioides* Sherb., *Gibberella intricans* Wollenw. (*F. equiseti*), *Gibberella zeae* (Schwein.) Petch (*Fusarium graminearum*), *Gibberella tricincta* El-Gholl, McRitchie, Schoult. & Ridings (*Fusarium tricinctum*), and *Gibberella moniliformis* Wineland (*Fusarium verticillioides*). These lactones possess estrogenic and anabolic activity as a result of the chemical similarity of this mycotoxin to 17β-estradiol, the principal hormone of the human ovary. The reduced form of zearalenone, zearalanol, is an anabolic agent for beef cattle.[427] In several assays, the binding of zearalenone to estrogen receptors was approximately 20-fold lower than 17 β-estradiol.[427] Zearalenone is a natural contaminant of corn and occasionally appears in cereals and feeds depending on climatic conditions. Low temperatures (12 °C–14 °C/~54 °F–57 °F) enhance production of this mycotoxin. Zearalenone is a relative stable compound that requires harsh conditions (>12 days at 110 °C/230 °F in alkaline solution) to decompose.[351] In a sample of cornflakes, the zearalenone concentration was about 13 μg/kg.[428] Zearalenone concentrations ranging from 8–53 mg/kg contaminated South African beer produced from corn and sorghum. Because of the large doses of zearalenone required to excrete this mycotoxin in the milk of lactating cows, contamination of commercial milk with zearalenone is unlikely.[429] The estimated mean daily consumption of zearalenone by Canadians is about 0.05 μg/kg, which risk assessment data suggests is a safe dose.[427]

In several *Fusarium* species, zearalenone appears to control sexual development. Mammals and, in particular, swine are particularly sensitive to its estrogenic activity, displaying vulval, uterine, and breast enlargement as well as ovarian atrophy, vaginal prolapse, and infertility at feed levels of 1 mg/kg. There are no reports of hyperestrogenism in humans.

Chapter 46

ALOE VERA
[*Aloe vera* (L.) Burm. f.]

HISTORY

Clay tablets discovered in Mesopotamia suggest the aloe vera was a pharmaceutical agent for early civilizations dating back to 1750 BC.[1] Aloe vera is a native plant of the Mediterranean region that extrudes a juicy clear mucilaginous gel (aloe vera gel) from the leaves and a yellow exudate containing high concentrations of anthraquinone compounds. Since Roman times, the latter agent has been ingested as a strong cathartic and medicinal purge; the gel has been applied to reduce infection and improve wound healing. Other uses of aloe vera in folk medicine have included the treatment of skin wounds, burns, hyperlipidemia, diabetes, and obesity.[2]

BOTANICAL DESCRIPTION

There are over 360 species in the genus *Aloe*. Of these species, plants used for medicinal purposes besides *A. vera* are relatively few including Cape aloe from South Africa (*A. ferox* Miller), Curacao aloe (*A. vera, Aloe barbadensis* Miller), candelabra aloe (*Aloe arborescens* Miller), and Zanzibar or Perry's aloe (*Aloe perryi* Baker).

Common Name: Aloe Vera

Scientific Name: *Aloe vera* (L.) Burm. f. *(A. barbadensis* Miller*)*

Botanical Family: Aloeaceae (formerly Liliaceae, lily family)

Physical Description: Aloe vera is an evergreen, perennial, succulent (cactus-like) plant that has gray-green, simple, lance-shaped leaves with a pointed apex (lanceolate). The leaves do not have stalks (petioles). The margins have small grayish teeth. The leaves are arranged alternately to form a rosette above a very short stem. The main rosette reaches approximately 2 feet (61 cm) in height, and the plant continually produces little offset rosettes. The flowers are regular, bisexual, yellow to orange in color, and appear in terminal series of flowers on lateral stalks (racemes). These flowers produce capsules with many flattened seeds. Figure 46.1 displays a specimen of the aloe vera plant.

Distribution and Ecology: Aloe adapts well to desert climates. This plant is native to Arabia and Madagascar, but the largest distribution occurs in South Africa. In the United States, aloe vera grows in the drier parts of Texas, Florida, Puerto Rico, and Hawaii.

EXPOSURE

Sources

This perennial succulent is a popular houseplant. The dried juice of aloe vera is a solidified substance originating in the cells of the pericycle and adjacent leaf parenchyma. After flowing spontaneously from the cut leaf, the fresh juice is dried with or without the aid of heat. Aloe vera gel is a clear, mucilaginous gel extracted from

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

FIGURE 46.1. *Aloe vera* (L.). Photograph Courtesy of Paul Auerbach, MD. See color insert.

the parenchymatous cells in the leaves of *Aloe vera* (L.) Burm. f. Curacao; Barbados aloe is a dark chocolate-brown, dried juice extracted from *Aloe vera* (L.) Burm. f.; Cape aloe is a dark brown or greenish brown, dried juice derived from *A. ferox* Mill. or from hybrids of *A. ferox* and other aloe plants (e.g., *A. africana* Mill., *A. spicata* Baker).

Medicinal Uses

Traditional

Traditional uses of aloe vera include the treatment of arthritis, asthma, fungal infections, digestive and bowel disorders (e.g., constipation), lupus erythematosus, skin disorders (e.g., seborrheic dermatitis), musculoskeletal injuries, and gastroduodenal ulcers. Other uses include application as an insect repellant and the treatment of diabetes mellitus, antihemorrhoidal agent, gout, tuberculosis, gonorrhea, headaches, and eczema.[3]

Current

Aloe vera gel is a constituent of food and drink, an antiinflammatory in cosmetics and topical agents, and a moisturizer in lotions.[4] Although experimental studies[5,6] and anecdotal case reports suggest a wide range of medical applications for aloe vera gel,[7,8] the clinical effectiveness of the oral or topical application of this substance remains unsubstantiated.[9,10] In an experimental study, aloe vera did not alter the erythema or vasodilation produced by UVB radiation up to 24 hours after exposure.[11] Clinical trials did not demonstrate the efficacy of aloe vera gel for the treatment of radiation burns[12] or aphthous stomatitis.[13] The dried latex form of aloe is an approved oral agent based on the cathartic actions of aloe-emodins and other anthraquinone compounds. The plant portion most commonly used by the pharmaceutical industry is the latex, which stains clothes and fixtures purple.

Regulatory Status

The German Commission E approves the use of aloe for the limited (1–2 weeks) treatment of constipation. The US Food and Drug Administration (FDA) does not permit the use of aloe products as nonprescription drugs for treatment of constipation because of the lack of documented efficacy and safety. Aloe products are controlled as dietary supplements in the United States.

PRINCIPAL INGREDIENTS

Chemical Composition

The aloe vera gel is derived from the thin-walled mucilaginous cells of the leaves that contain a variety of carbohydrate polymers (glucomannans) along with organic and inorganic compounds.[14] Peripheral bundle sheath cells of aloe vera produce a bitter, yellow latex called aloe juice, aloe sap, or aloes. The aloe vera plant contains at least 75 potentially pharmacologically active compounds including vitamins, minerals, sugars, amino acids, enzymes, lignans, saponins, and salicylic acids as listed in Table 46.1.[15] The major constituent (i.e., about 15–40%) of dried aloe is a mixture of two diastereomeric C-glucosides [aloin A (10S) and aloin B (10R)], formerly known as barbaloin. Hydroxyaloin is a minor constituent (i.e., about 3%).

In a study of Cape aloes in South Africa, the major constituents were aloeresin A, aloesin, and aloin A and B.[16] These compounds accounted for 70–97% of the total dry weight of *Aloe capensis* (*ferox*) leaf exudate with aloin content of the juice samples averaging about 21%. The polysaccharides in the gel consist of glucomannans, mannans, and pectins with a wide range of molecular weights. The major carbohydrate fraction of aloe gel contains acemannan substances, which are β-1,4-linked acetylated mannan compounds interspersed with *O*-acetyl groups. Animal studies indicate that these compounds demonstrate relatively low toxicity.[17] Aloe vera gel does not contain the strong cathartics (anthraquinone compounds) present in aloe saps. Toxic low-molecular-weight compounds are present in aloe vera gel extracts,[18] but the concentration and pharmacological significance these substances remain unclear.

Physiochemical Properties

Figure 46.2 displays the structure of the common constituents of the dried latex extracted from the leaves of *Aloe* species. This extract has an aromatic aroma and

TABLE 46.1. Classification of Constituents of Aloe Vera

Class	Compounds
Anthraquinone	Aloe-emodin, aloetic acid, aloin A and B, hydroxyaloin, anthranol, chrysophanic acid, cinnamic acid ester, emodin, resistannol
Enzymes	Amylase, catalase, cyclooxygenase, lipase, alkaline, phosphatase, carboxypeptidase, oxidase
Essential amino acids	Isoleucine, leucine, lysine, methionine, phenylalanine, threonine, valine
Inorganic compounds	Calcium, chlorine, chromium, copper, iron, magnesium, manganese, potassium sorbate, sodium, zinc
Nonessential amino acids	Alanine, arginine, aspartic acid, glutamic acid, glycine, histidine, hydroxyproline, proline, tyrosine
Saccharides	Aldopentose, cellulose, glucose, mannose, L-rhamnose
Vitamins	B_1, B_2, B_6, C, choline, folic acid, α-tocopherol, β-carotene
Miscellaneous	Arachidonic acid, cholesterol, gibberellin, lectin-like substance, lignans, salicylic acid, β-sitosterol, steroids, triglycerides, uric acid

bitter taste. Aloin A and B undergo rapid decomposition in solution, particularly in basic solutions. Aloe extracts have good emollient and moisturizing properties; however, there are limited data on the efficacy of these preparations. The compounds in aloe responsible for the physiological properties used for medicinal purposes remain uncertain.[19] Table 46.2 lists some physiochemical properties of aloin (CAS RN: 1415-73-2).

TABLE 46.2. Some Physiochemical Properties of Aloin

Physical Property	Value
log P (octanol-water)	0.550
Water Solubility	8,300 mg/L (20 °C/68 °F)
Vapor Pressure	5.28E-21 mm Hg (25 °C/77 °F)
Henry's Law Constant	2.61E-21 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	2.77E-10 cm^3/molecule-second (25 °C/77 °F)

Mechanism of Toxicity

The laxative effects of aloe result primarily from the effects of two main diastereomeric 1, 8-dihydroxyanthracene glycosides (aloin A and B), which are metabolized into the main active metabolite, aloe-emodin-9-anthrone, by colonic bacteria. This compound is a gastrointestinal stimulant and irritant, similar to senna.[20] Aloe-emodin-9-anthrone reduces fluid absorption from the fecal mass by stimulating colonic motility in addition to increasing water content in the large intestine, probably by inhibition of Na^+/K^+-adenosine triphosphatase or chloride channels.

DOSE RESPONSE

The daily laxative dose for adults and children over 10 years old is 0.04–0.11 g (Curacao or Barbados aloe) or 0.06–0.17 g (Cape aloe) of the dried juice, corresponding to 10–30 mg hydroxyanthraquinones per day, or 0.1 g as a single dose in the evening.[21] The recommended use of this laxative dose is limited to 1–2 weeks.

TOXICOKINETICS

The cathartic action of aloe usually begins at least 6–24 hours after ingestion. The absorption of aloin A and aloin B in the upper gastrointestinal tract is minimal, but animal studies indicate that bacteria metabolize these compounds to an active metabolite, aloe-emodin-9-anthrone, in the colon.[22]

CLINICAL RESPONSE

In the dried latex form, the aloe-emodins and other anthraquinone compounds are strong cathartics. Mucous membrane irritation may occur, but serious systemic symptoms following ingestion are unlikely. Rare case reports document the occurrence of relatively minor local reactions (eczematous and papular dermatitis) following the chronic oral or topical use of aloe preparations by hypersensitive patients.[23,24] The application of aloe vera preparations to skin during periods of enhanced susceptibility to dermal injury (e.g., dermabrasion, chemical peel) was associated with immediate local pain, erythema, and edema.[25] These adverse effects generally resolve promptly following cessation of use. There are limited data on the oral toxicity of *Aloe vera*, but systemic toxicity has not been associated with the oral administration of extracts of *A. vera* with the exception of the strong cathartic actions from the ingestion of the dried latex (aloe sap) containing anthraquinone compounds. Based on animal studies, the genotoxic risk of aloe-emodin is small.[26]

DIAGNOSTIC TESTING

A reversed-phase gradient elution system with high-performance liquid chromatography (HPLC) is available to simultaneously separate a variety of components in *Aloe* species including aloesin and aloeresin A.[27,28] Methods for the detection of anthraquinone compounds [aloe-emodin, aloin-A (barbaloin)] in aloe-based products include liquid chromatography/mass spectrometry and liquid chromatography with diode array detection in the UV range.[29] False-positive results for urinary urobilinogen can occur during aloe use because some anthranoid metabolites discolor the urine.

TREATMENT

Treatment is supportive. Based on limited data, the primary toxic reaction to aloe vera is catharsis. Therefore, patients with suspected toxicity should be evaluated for fluid and electrolyte balance if clinically significant diarrhea occurs. Decontamination measures are unnecessary.

Chapter 47

ARISTOLOCHIC ACID and CHINESE HERB NEPHROPATHY

HISTORY

Mu Tong is an ancient Chinese herb that was derived from *Akebia* species until the early 20th century.[1] After that time, *Clematis* species became the main source of Mu Tong until the 1950s. Then, *Aristolochia manshuriensis* became the main component of this herb. Since the substitution of *Aristolochia manshuriensis* for *Clematis* species in preparations of Mu Tong, case reports in China associated the development of renal failure with the use of Mu Tong.[2] Prior to the use of *Aristolochia manshuriensis* in preparations of Mu Tong, renal dysfunction was not reported in Chinese herbal formularies as a complication of the ingestion of Mu Tong.[1]

In 1993, Vanherweghem et al reported a rapidly progressive, fibrosing interstitial nephritis in two young women, who had been treated with an herbal slimming medication supposedly containing *Stephania tetrandra* and *Magnolia officinalis*.[3] An investigation revealed that seven other women, who also followed a slimming regimen at the same Brussels medical clinic, were admitted to a renal clinic for renal dialysis between 1991 and 1992. Renal biopsies from eight of the nine cases demonstrated extensive interstitial fibrosis without glomerular lesions. Phytochemical analysis of the pills from this weight-reduction clinic detected the presence of aristolochic acids instead of tetrandrine, and this substitution suggested the contamination of these herbal preparations by *Aristolochia fangchi*. Case reports described the development of interstitial nephritis following the use of other Chinese herbal preparations that contained aristolochic acid.[4] In 1999, a case report described two cases of end-stage renal failure in the United Kingdom following the use of Chinese herbal teas containing aristolochic acid.[5] Additional cases of Chinese herb (aristolochic acid) nephropathy occurred in Asia, Spain, and France.[6,7]

BOTANICAL DESCRIPTION

The genus *Aristolochia* contains over 400 species of perennial herbs and shrubs. Misidentification of *Aristolochia* species as a nonaristolochic acid–containing plant species occurs with a variety of Chinese herbs from *Akebia, Asarum, Clematis*, and *Cocculus* genera. Aristolochic acids also occur in several species of butterflies (e.g., *Atrophaneura, Battus, Pachliopta, Troides*), which feed on *Aristolochia* species.

Common Name: Kou-boui, Guang Fang Ji

Scientific Name: *Aristolochia fangchi* Y. C. Wu ex L. D. Chow & S. M. Hwang

Botanical Family: Aristolochiaceae (birthworts)

Physical Description: This herb is a perennial climbing vine with a slender, gray-brown stem that contains brown villi. The oblong or ovate-shaped leaves are petioled and relatively large, 3–11 cm (~1–4 in.) long and 2–6 cm (0.8–2.4 in.) wide. The tubular, purple flower is 2–3 cm (~.8–1.2 in.) long with yellow spots. The flowers bloom in May and June. The capsules contain many seeds.

Distribution and Ecology: The Aristolochiaceae family comprises seven genera of herbs and shrubs

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

distributed throughout tropical, subtropical, and some northern temperate zones of Asia, Africa, South America, and North America. In Europe, *Aristolochia clematitis* is indigenous to the Mediterranean region. *A. fangchi* inhabits valleys near streams.

EXPOSURE

Sources

Aristolochic acid occurs primarily in herbs from the genus *Aristolochia* including *A. fangchi* (root), *A. manshuriensis* (stem, Guan Mu Tong), *A. contorta* Bge. (fruit or herb, Ma Dou Ling), and *A. debilis* Sieb et Zucc (radix, fruit, or herb). Table 47.1 lists some Chinese herbs, which contain ingredients from *Aristolochia* species. Other aristolochic acid-containing species include some *Asarum* species including *A. himalaicum* Hook. f. & Thomson ex Klotzsch (Xi Xin), *A. crispulatum* C. Y. Cheng & C. S. Yang, and *A. splendens* (F. Maekawa) C. Y. Cheng & C. S. Yang.[8] Chinese herb nephropathy develops after the chronic use of herbal preparations (e.g., Kampo prescriptions, *Stephania tetrandra*, *Magnolia officinalis*) contaminated with aristolochic acid-containing herbs. The *Aristolochia fangchi* root or the *Aristolochia manshuriensis* stem may be substituted for the Japanese herbal medicine *Akebia* stem or *Sinomenium* stem in Chinese-produced pharmaceutical preparations and health foods. Aristolochic acid is present in a variety of Chinese herbal preparations for weight reduction. Some raw Chinese herbs (Guan Mu Tong, Ma Dou Ling, Guang Fang Ji) still contain aristolochic acid I despite the ban on commercial products containing aristolochic acids.[9] A Swiss study of 42 Chinese herbal preparations for slimming demonstrated the presence of aristolochic acid I in four preparations in concentrations up to about 0.04%.[10]

Medicinal Uses

Traditional

The use of *Aristolochia* species is an ancient treatment for a wide variety of diseases including dysentery, skin infections, phlebitis, cancer, and arthritis.[11,12] Stems of *A. manshuriensis* are used in traditional Chinese medicine as a cardiotonic herb. Medicinal uses for the mature fruits of *A. debilis* (madouling) include the treatment of hypertension, tuberculosis, and snake bites.[13] In West Africa, *A. albida* is a traditional treatment for dysentery, colic, skin lesions, and snake bites.[14] The dry root of *A. indica* is an Indian folk medicine for inducing abortions. Charrua is a hydroalcoholic extract of *Aristolochia argentina* that is a traditional treatment for hemorrhoids and diarrhea as well as being a folk treatment for "purifying the blood."

Regulatory Status

Many countries now ban the use of herbal products containing aristolochic acid. After reports on the development of renal failure in Belgian patients given weight loss products containing aristolochic acid, the US Food & Drug Administration (FDA) issued a consumer advisory that recommended the cessation of use of any product containing aristolochic acid. Later in 2001, the FDA detained products suspected of containing aristolochic acid. Similar bans are now in effect in Canada, Australia, and parts of Europe including the United Kingdom.

PRINCIPAL INGREDIENTS

Chemical Composition

Aristolochia species contain a variety of aristolochic acids, aristololactams, aristoquinolines, aristogins, and sesquiterpenes in varying amounts depending on the species, plant part, and the geographic location.[15,16] In three commercial samples of *A. fangchi* (kou-boui) and *A. manshuriensis* (kan-mokutsu), the aristolochic acid I (CAS RN: 313-67-7) content ranged from 0.01–0.22% and 0.17–0.88%, respectively, compared with about 0.08–0.11% in samples of *A. debilis*.[17] The amount of aristolochic acid II (CAS RN: 475-80-9) was approximately 10% of the aristolochic acid I concentration as measured by high performance liquid chromatography (HPLC). As measured by capillary zone electrophoresis, the content of aristolochic acid I and II in samples of radix aristolochiae fangchi was approximately 0.06% and 0.03%, respectively.[18] Figure 47.1 displays the chemical structures of aristolochic acids I and II. Species of

Aristolochic Acid I	OCH_3
Aristolochic Acid II	H

FIGURE 47.1. Chemical structures of aristolochic acid I and II.

Aristolochia (e.g., *A. macrophylla, A. serpentaria*) in North America also contain detectable concentrations of aristolochic acids I and II. Samples from *A. macrophylla* Lam. and *A. serpentaria* L. contained 0.39% and 0.13%, respectively, aristolochic acid I by dry weight, while samples of *Asarum canadense* L. contained aristolochic acid I concentrations ranging from non-detectable to 0.037% dry weight.[19] However, these concentrations of aristolochic acids are low compared with *Aristolochia* species. Aristolochic acid II was not detected in samples of *Asarum canadense*. Seeds of *A. clematitis* (birthwort) contain about 0.65% aristolochic acid.[20] Essential oils from *Aristolochia* species contain a variety of monoterpene (camphanes, methanes, pinanes), diterpene (geranylgeranyl pyrophosphate derivatives), and sesquiterpene (aristolanes, bicyclogermacranes, cadinanes, germacranes) compounds.[11]

Physiochemical Properties

Aristolochic acids are slightly soluble in water with melting points in the range of 281 °C–286 °C (538 °F–547 °F). Aristolochic acids are nitrophenanthrene carboxylic acid derivatives that cause extensive necrosis of the squamous epithelium in the forestomach of rats, followed by hyperplasia, papilloma formation, and invasive squamous cell carcinoma.[21] Aristolochic acid I is a direct-acting mutagen in *Salmonella typhimurium* strains TA100, TA102, TA1537, and TM677, but this compound was not active in the nitroreductase-deficient strains TA98NR and TA100NR.[22]

Mechanism of Toxicity

Aristolochic acids are the probable proximal renal tubular toxin and carcinogen in Chinese herb associated nephropathy.[23] The activation of the metabolite of aristolochic acid I, aristolactam I, by peroxidase causes the formation of the major adducts associated with the development of urothelial carcinoma following the administration of aristolochic acid-containing herbs.[24] The cytochrome P450 isoenzymes, CYP1A1, CYP1A2, and possibly other CYP450 isoenzymes activate aristolochic acids to cyclic reactive nitrenium ions that form covalent DNA adducts on guanine and adenosine.[25] The oral administration of aristolochic acid to female rats causes renal lesions similar to the cases of aristolochic acid nephropathy, manifest by renal tubular necrosis, proteinuria, glucosuria, and azotemia.[26] The administration of decoctions from Chinese herbs [e.g., *Akebia quinata* (Houtt.) Dcne.] without detectable quantities of aristolochic acid did not cause renal lesions. There was evidence of renal toxicity, but not liver or bladder lesions in NIH mice administered the equivalent dose of up to 4 g raw herb (*Aristolochia manshuriensis*, 0.5–1% aristolochic acid) daily for 8 weeks.[27] This dose was equivalent to approximately 40 times the daily dose used in traditional Chinese medicine. The initial damage in the kidney occurs in the brush borders of the S3 segment of the proximal renal tubules, leading to the release of the lysosomal enzyme, *N*-acetyl-β-D-glucosaminidase, and increased urinary excretion of filtered microproteins (e.g., retinol-binding protein, β_2-microglobulin, α_1-microglobulin, Clara cell protein).[28] Animal studies suggest that there are substantial species differences in susceptibility to the renal damage caused by aristolochic acids.[29]

DOSE RESPONSE

The risk of developing renal failure and urothelial carcinoma after ingesting aristolochic acid is dose-related.[30] Cumulative doses of aristolochic acid exceeding 200 g were associated with increased risk of developing urothelial cancer.[31] Retrospective evaluation of patients with Chinese herb nephropathy indicated that the amount of aristolochic acid ingested by some of these patients was approximately 10 mg/kg body weight.[3] In female Wister rats, the administration of a single dose of 10 mg aristolochic acid/kg body weight caused renal dysfunction within 3 days manifest by necrosis of the renal tubular epithelium, elevation of plasma creatinine, and increased markers of renal tubular function (protein, *N*-acetyl-β-glucosaminidase, γ-glutamyl transferase, malate dehydrogenase).[32] Single oral doses of 120–300 mg/kg caused severe acute tubular necrosis within a few days. The intraperitoneal administration of 0.1 mg aristolochic acid/kg body weight to female New Zealand white rabbits 5 days/week for 17–21 months was associated with the development of renal hypocellular interstitial fibrosis.[33] Three of 12 rabbits in the treatment group developed tumors of the urinary tract. No signifi-

cant pathologic changes were detected in 10 control rabbits.

TOXICOKINETICS

The principal metabolites of aristolochic acids are aristololactams, which are excreted in the urine and feces. The cytochrome P450 isoenzymes (CYP1A1, CYP1A2) and NADPH:CYP reductase metabolize aristolochic acids to the putative reactive cyclic nitrenium ion responsible for formation of the adducts, 7-(deoxyadenosin-N6-yl) aristolactam I, 7-(deoxyguanosin-N2-yl) aristolactam I, and 7-(deoxyadenosin-N6-yl) aristolactam II.[34] Other enzymes involved in the biotransformation of aristolochic acid to reactive nitrenium ions include NADPH:P450 reductase, NAD(P)H:quinone oxidoreductase, xanthine oxidase, and peroxidases.[35]

CLINICAL RESPONSE

Chinese herb nephropathy is a chronic renal disease characterized by progressive tubulointerstitial fibrosis that results in moderate to end-stage renal disease. Animal studies indicate that the S3 segment of the proximal tubule is the primary target with initial loss of the proximal tubule brush border.[36] Initially, the interstitial fibrosis begins in the proximal tubules of the superficial cortex of the kidney and spreads to the deep cortex. Dysplastic and neoplastic changes of the urothelial epithelium are also associated with this syndrome. In a study of 39 patients with aristolochic acid-induced nephropathy, only 2 patients had normal urothelium in their surgically removed kidneys.[31] There were 18 cases of urothelial carcinoma, which included 17 cases of carcinoma of the ureter and/or the renal pelvis and one case of papillary bladder tumor. Nineteen of the remaining patients had mild-to-moderate urothelial dysplasia. Tissue samples from the kidneys and ureters of these patients all had detectable concentrations of aristolochic acid-DNA adducts. The International Agency for Research on Cancer (IARC) lists herbal remedies containing plant species of the genus *Aristolochia* as carcinogenic to humans (Group 1) and naturally occurring mixtures of aristolochic acids as probably carcinogenic to humans (Group 2A).[37]

The contamination of food by seeds of *Aristolochia clematitis* is a possible cause (i.e., along with the mycotoxin, ochratoxin A) of Balkan endemic nephropathy, which is a familial chronic tubulointerstitial renal disease with slow progression to end-stage renal failure.[38] The presence of DNA adducts derived from aristolochic acid in renal tissues of patients with Balkan endemic nephropathy and in transitional cell cancers from this population suggest that chronic dietary exposure to aristolochic acids is a significant risk factor for this disease and the associated urothelial cancers.[39]

DIAGNOSTIC TESTING

Analytical Methods

Aristolochic acid is detectable in the 1 ppm range by HPLC with UV detection (390 nm) or photodiode array detector (DAD), liquid chromatography (LC) with electric ionization mass spectrometry,[40] and reversed-phase LC coupled with atmospheric pressure chemical ionization tandem mass spectrometry (MS) using positive ion detection.[41,42] The limits of detection for aristolochic acids and aristololactams using HPLC with DAD-UV (260 nm) were approximately 10–15 ng/mL.[43] Targeted analysis by LC/serial MS using a quadrupole ion-trap mass spectrometer can detect aristolochic acid in herbal samples contaminated with 0.1% dry weight *Aristolochia manshuriensis*.[44] Capillary zone and micellar electrokinetic electrophoresis are rapid methods for the determination of aristolochic acid content with limits of detection in the range of 10 μg/g material and 1 μg/mL, respectively.[15,45] HPLC and liquid chromatography/mass spectrometric methods are available for distinguishing aristolochy acid-containing species from the nontoxic species, e.g., *Stephania tetrandra*, based on the detection of aristolochic acid I (*Aristolochia* spp., *Asarum* species), tetrandrine, and/or fangchinoline (*S. tetrandra*).[46]

Biomarkers

Aristolochic acid-DNA adducts are specific markers of exposure to aristolochic acid in the kidneys and in the ureters after removal of the native organs for renal transplantation. The major DNA adduct of aristolochic acid, 7-(deoxyadenosin-N6-yl)-aristolactam I, is detectable in kidneys and ureters from patients with Chinese herb nephropathy using the nuclease P1 version of the ^{32}P-postlabeling method.[47] Other detectable minor adducts include 7-(deoxyguanosin-N2-yl)-aristolactam I and 7-(deoxyadenosin-N6-yl)-aristolactam II. The major DNA adduct is detectable at least 5–6 years after discontinuation of aristolochic acid-contaminated herbs.[48]

TREATMENT

Treatment is supportive. Patients should be evaluated for evidence of renal dysfunction and electrolyte imbalance. Dialysis and/or renal transplantation are therapeutic options for the treatment of end-stage renal

disease associated with the chronic use of aristolochic acid-containing herbs.

Chapter 48

BLACK COHOSH
(*Actaea racemosa* L.)

HISTORY

This plant was first described by Plukenet in 1696, and Linnaeus later classified black cohosh as *Actaea racemosa*.[1] Although Pursh later reclassified this plant into the genus *Cimicifuga*, recent DNA analysis resulted in the classification of black cohosh as *Actaea racemosa*.[2] Black cohosh is a native herb of eastern North America with a long history of traditional use by Native Americans, primarily for amenorrhea and menopause. In the Eclectic Dispensary of 1852, black cohosh was a treatment for joint pains, headache, inflammation, neuralgia, labor pains, and dysmenorrhea. Black cohosh was an ingredient of Lydia Pinkham's Vegetable Compound, which was a popular remedy for "female complaints" during the early 20th century. A fluid extract of black cohosh was listed in the US National Formulary from 1840 until 1946.

BOTANICAL DESCRIPTION

About 10 species of *Actaea* exist in the northern temperate zones of the world. The principal species in China are *A. dahurica, A. foetida*, and *A. heracleifolia*, whereas *A. acerina, A. japonica*, and *A. simplex* are the major species in Japan. Black cohosh should be distinguished from closely related species including blue cohosh [*Caulophyllum thalictroides* (L.) Michx.], summer cohosh or mountain bugbane (*Cimicifuga americana* Michx.), white cohosh or white baneberry (*Actaea pachypoda* Ell.), and red cohosh or red baneberry [*Actaea rubra* (Ait.) Willd.].

Common Name: Black Cohosh, Cohosh, Black Snakeroot, Squawroot, Rattle Weed, Rattle Root, Bugbane

Scientific Name: *Actaea racemosa* L. (formerly *Cimicifuga racemosa*)

Botanical Family: Ranuculaceae (buttercup)

Physical Description: Black cohosh is an erect perennial wildflower that produces a clump of quadrangular stems up to 3 ft (~90 cm) tall. The large, alternate, three-pinnately compound leaves have saw-tooth edges. Greenish-white, petalless flowers emerge from June through September. The rhizome is black and the surface is knotted. Seed pods remain on the raceme during the winter, and a distinctive noise occurs when the wind blows on these seed pods. This noise accounts for the common name of rattle weed.

Distribution and Ecology: *A. racemosa* occurs in the deciduous forests of North America as well as Europe. This plant grows in rich, shady soil in eastern North America from southern Ontario to northern Georgia and west to Arkansas, Missouri, and Wisconsin. The eastern United States and Canada are the sources for commercial stocks of black cohosh. The distribution of black cohosh is similar to blue cohosh, which inhabits the deep rich loam of shady woods from New Brunswick to South Carolina and westward to Nebraska, particularly in the Allegheny Mountain region.

EXPOSURE

Sources

A. dahunica is the source of the traditional chinese medicine, sheng ma. Native Americans used the dried roots and rhizomes of *A. racemosa* for a variety of conditions ranging from menstrual problems to rattlesnake bites. Some commercial products of black cohosh contain Asian species of *Actaea* rather than *Actaea racemosa*. In a study of 11 commercial black cohosh products analyzed by high performance liquid chromatograph (HPLC)/photodiode array detection and liquid chromatography with selected ion monitoring mass spectrometry, 3 of the 11 samples contained the marker (cimifugin) for Asian *Actaea* species rather than the marker (cimiracemoside C) for *Actaea racemosa*.[3]

Medicinal Uses

Traditional

Traditional uses for black cohosh include the treatment of menopause and related symptoms (anxiety, insomnia, amenorrhea, hot flashes, depression). Cherokee and Iroquois Indians used this herb for rheumatism, sore throat, malaise, kidney diseases, and diseases related to the female reproductive system.[1] In Chinese medicine, sheng ma refers to rhizomes of other *Actaea* species [e.g., *Actaea dahurica* (Turcz. ex Fisch. & C. A. Mey.) Franch., *A. foetida* L., *A. heracleifolia* (Kom.) J. Compton] that are used for infectious diseases, uterine and rectal prolapse, fever, inflammation, and pain.

Current

Black cohosh is the principal herb used to treat menstrual disorders. An ethanolic extract of the rhizome of black cohosh is marketed as a 20 mg-tablet of Remifemin® (Enzymatic Therapy, Inc., Green Bay, WI), which contains 1 mg of triterpenes calculated as 27-deoxyactein. This commercial product is a dried 40% isopropanol extract of the roots and rhizomes of black cohosh (*Actaea racemosa*). The efficacy of black cohosh extracts for the treatment of menstrual symptoms remains unclear.[4] A double-blind, randomized, placebo-controlled clinical trial did not demonstrate a statistically significant, subjective improvement in hot flashes in the treatment group (20 mg *Cimicifuga racemosa* twice daily), when compared with placebo during the 4-week cross-over study.[5]

Regulatory Status

The German Commission E approved the use of black cohosh root for premenstrual discomfort, dysmenorrhea, and menopausal symptoms (hot flashes, diaphoresis, sloughing of skin, atrophic vaginitis, irritability, depression).

PRINCIPAL INGREDIENTS

Chemical Composition

Black cohosh contains alkaloids, at least 20 phenolic compounds (cimicifugic acid A, B, E, and F, fukinolic acid, ferulic acid, isoferulic acid, fukiic acid, and caffeic acid caffeic acid),[6,7] organic acids, palmitic and oleic acids, tannins, resins, volatile oils, flavonoids, and over 43 terpenoid glycosides (e.g., actein, 23-epi-26-deoxyactein, 26-deoxyactein, 12-acetylactein, cimiracemoside A, cimiaceroside C, cimigenoside, cimicifugoside H-1, cimicifugoside M).[8–10] In particular, black cohosh contains substantial concentrations of triterpene glycosides and caffeic acid derivatives. The caffeic acid derivatives consist of esters between the carboxyl group of caffeic acid, ferulic acid or isoferulic acid, and the hydroxyl group of fukiic or piscidic acid. Analysis of black cohosh extracts by HPLC/electrospray ionization tandem mass spectrometry demonstrated a variety of caffeic acid derivatives including caffeic acid, cimicifugic acid A, B, E, and F, dehydrocimicifugic acid A and B, ferulic acid, isoferulic acid, and fukinolic acid.[11] Figure 48.1 displays the chemical structures of some triterpene glycosides and phenolic compounds in black cohosh. Nonrandom sampling of extracts of an 85-year old sample of black cohosh contained triterpene glycoside concentrations ranging from about 3.1–5.2%, depending on the extraction method, whereas the amount of phenolic compounds range from approximately 5.2–5.8%.[12] In contrast to data from early studies on black cohosh, this herb and the root extract do not contain significant quantities of the estrogenic isoflavone, formononetin, or ononin (formononetin-7-glucoside).[13] Total phenolic compounds (caffeic acid, ferulic acid, isoferulic acid fukinolic acid, cimicifugic acid A, B, E, and F) in recently dried roots and rhizomes of black cohosh accounted for approximately 0.62% of the plant as measured by HPLC with diode array detection.[14]

Physiochemical Properties

Triterpene compounds are relatively stable compounds with the exception of compounds containing a free carboxylic group.[15] Additionally, triterpene compounds are not stable at the extreme ranges of pH. The total amount

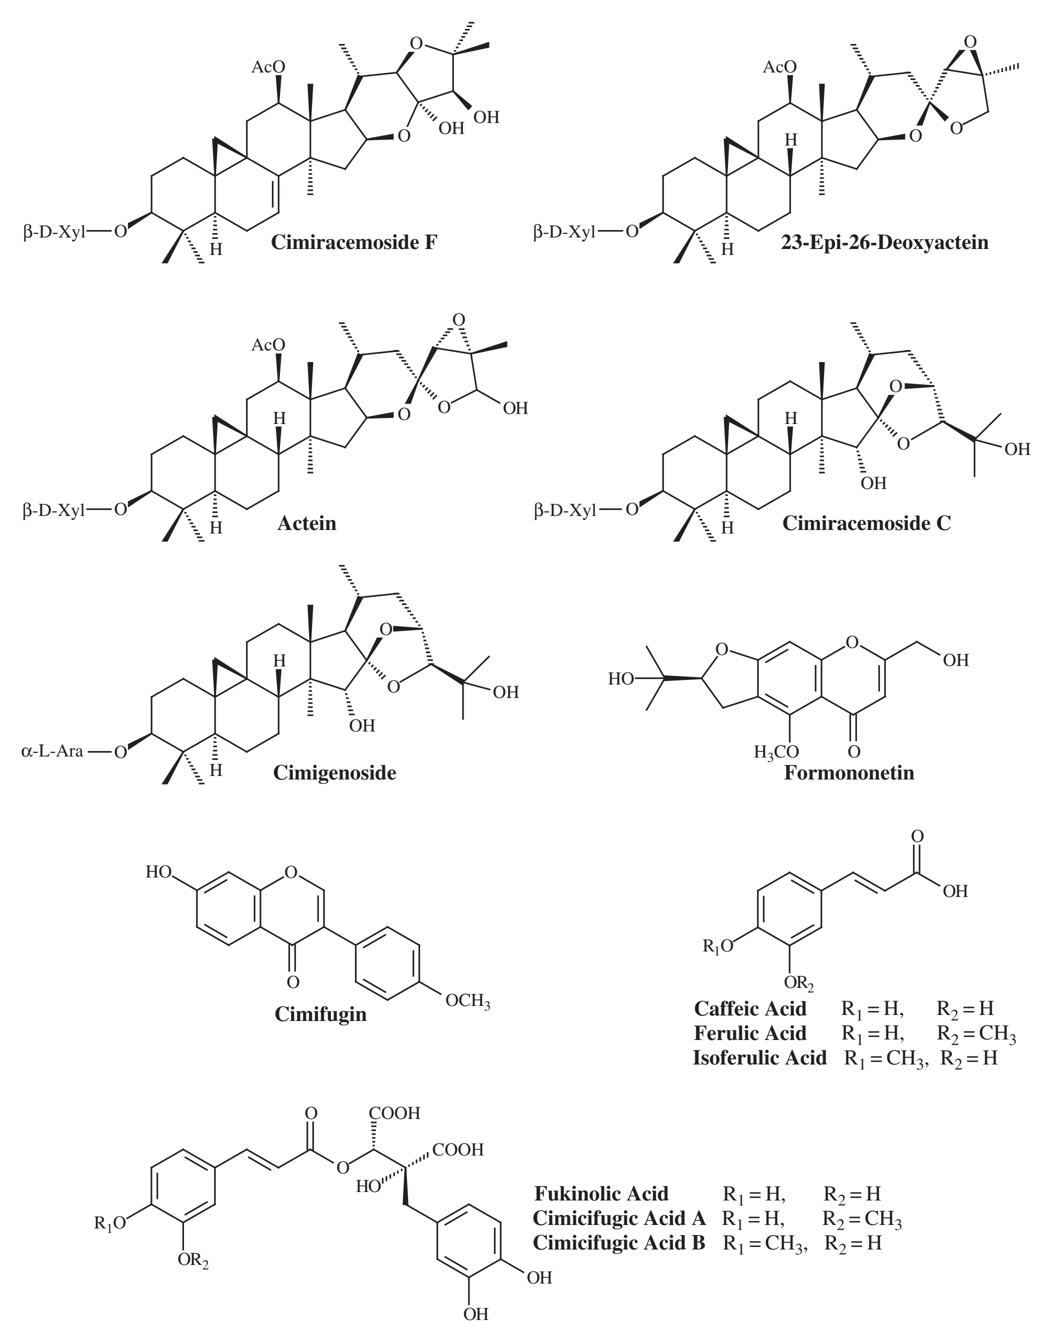

FIGURE 48.1. Chemical structures of triterpene glycosides and phenolic compounds in black cohosh. Adapted from Jiang B, et al. Evaluation of the botanical authenticity and phytochemical profile of black cohosh products by high-performance liquid chromatography with selected ion monitoring liquid chromatography-mass spectrometry. J Agric Food Chem 2006;54:3243.

of phenolic compounds in a 85-year-old sample of black cohosh stored under varying environmental conditions at a botanical garden was 4.25% compared with 5.68% in a modern sample of black cohosh.[12]

Mechanism of Toxicity

The mechanism of action (e.g., estrogenic activity, reduction of leuteinizing hormone) of black cohosh has not been defined, and evidence of the efficacy for the treatment of menstrual disorders is inconclusive.[16,17] However, the effects of black cohosh probably are not mediated through estrogen receptors.[18] Although earlier studies suggested that components in black cohosh have estrogenic activity,[19] more recent *in vitro* evidence indicates that extracts of black cohosh do not affect the estrogen receptors.[20,21] A study of ovariectomized Sprague-Dawley rats given a 40% isopropanol extract of black

cohosh for 2 weeks with or without estradiol did not detect any differences in uterine weight or vaginal cellular cornification in the rats treated with black cohosh.[22] Subsequent testing of this extract against 10 subtypes of the serotonin receptor revealed strong binding to the 5-HT_{1A}, 5-HT_{1D}, and 5-HT_7 subtypes. Analysis of the binding data indicted that components of the black cohosh extract acted as a competitive ligand of the 5-HT_7 receptor, suggesting that the extract was a partial agonist at the receptor.

DOSE RESPONSE

Medicinal Use

The typical treatment for menopausal symptoms is two 20-mg standardized tablets of the root extract (Remifemin®) twice a day. Each tablet is standardized to contain 1 mg of triterpene glycosides calculated as 27-deoxyactein. There are no definite clinical data that two 20-mg standardized tablets of the root extract (Remifemin®) twice a day is more effective than one 20-mg standardized tablet of the root extract (Remifemin®) twice a day. Some herbalists combine black cohosh with blue cohosh for the induction of labor.[1] Many studies demonstrating the effectiveness of black cohosh for the treatment of menopausal symptoms are open clinical trials. Most randomized, placebo-controlled, double-blind studies of supplements containing soy isoflavones and *A. racemosa* do not detect statistically significant effects of these supplements on climacteric symptoms in perimenopausal women as measured by the modified Kupperman Index and the Greene Climacteric Scale.[23] In a multicenter, randomized, placebo-controlled double-blind study of 122 menopausal women, the primary efficacy analysis using the Kupperman Index and the Menopause Rating Scale did not demonstrate the superiority of black cohosh administration (mean dose 42 mg daily) over placebo.[24] However, in the subgroup of women with a Kupperman Index ≥20, black cohosh use decreased the index 47% compared with 21% for placebo ($P < 0.018$). A prospective, randomized, double-blind evaluation of black cohosh extract on hot flashes in women, who had completed primary breast cancer treatment, demonstrated a statistically significant reduction of sweating in the treatment group compared with the controls.[25] However, all other improvements in symptoms including declines in the number and intensity of hot flashes were similar in both groups. A randomized, multicenter, double-blind clinical trial compared the efficacy and tolerability of the isopropanol extract of black cohosh in the treatment of climacteric complaints with placebo.[26] The isopropanol extract of black cohosh extract was more effective than placebo ($P < 0.001$) depending on time from symptom onset ($P = 0.014$) and follicle-stimulating hormone level ($P = 0.011$) based on Menopause Rating Scale units. The effect size (0.03–0.05) on the Menopause Rating Scale was similar to recent hormone replacement therapy study results.

Toxicity

Rare case reports associate the use of black cohosh as well as other herbs with the development of severe hepatotoxicity.[27] These effects probably result from idiopathic reactions rather than dose-related hepatotoxicity.

TOXICOKINETICS

Preliminary evidence suggests that ingredients in commercial black cohosh can inhibit CYP3A4 enzymes, and therefore drug interactions potentially can occur with the concomitant administration of drugs metabolized by the same isoenzymes.[28,29] However, there is no human data to confirm the interaction of black cohosh with drugs requiring metabolism by CYP3A4 enzymes. An *in vivo* study detected a statistically significant reduction in CYP2D6 activity after 4 weeks of therapy with black cohosh, but the magnitude of the effect was small and probably clinically insignificant.[30] This *in vivo* study did not detect any inhibition of black cohosh on CYP3A4. Other *in vivo* studies of volunteers receiving 40 mg black cohosh daily for 14 days indicated that supplementation with this extract did not alter digoxin pharmacokinetics (P-glycoprotein transporter)[31] or midazolam (CYP3A4) pharmacokinetics.[32]

CLINICAL RESPONSE

Adverse reactions associated with the clinical use of pharmacological doses of black cohosh typically are rare, mild, and reversible with most symptoms involving mild gastrointestinal (GI) upset.[33] The most common adverse effects are GI disturbances, rashes, headaches, dizziness, mastalgia, and weight gain.[34] Rare case reports associate the use of black cohosh with the development of severe hepatitis requiring liver transplantation. A case report temporarily associated one week of back cohosh use with the development of severe hepatitis and fulminant hepatic failure requiring liver transplantation.[27] The liver biopsy demonstrated changes consistent with an idiosyncratic, immunological reaction rather than a toxic reaction manifest by eosinophilia, moderate portal and lobular inflammation, bridging necrosis, and early fibrosis. There was no bile duct damage and no other apparent cause (e.g., alcohol, drug use, blood transfusion, viral infection) of the liver failure.

A 52-year-old women developed severe hepatitis one week after stopping the ingestion of an herbal preparation that contained black cohosh.[35] Over the following week, she developed hepatic encephalopathy and hepatorenal failure that required liver transplantation. The herbal preparation also contained pulegone, a known hepatotoxin. Another 50-year-old woman developed hepatic failure after taking 500 mg black cohosh root daily for 5 months.[36] The history and laboratory data did not suggest an alternate explanation for the liver failure. She underwent successful orthotopic liver transplantation with the explanted liver demonstrating cell necrosis, cholestasis, and bridging fibrosis. Although there are few data on the effect of black cohosh on liver function or serum hepatic aminotransferases, clinical studies on the efficacy of black cohosh to date have not detected clinically significant adverse effects on the liver.[37]

DIAGNOSTIC TESTING

Triterpene glycosides are difficult to analyze by conventional HPLC UV methods because of weak UV absorbance. Methods to detect these compounds in biological samples include evaporative light scattering detection (ELSD)/HPLC, atmospheric performance chemical ionization (APCI)-LC/MS,[8] and LC/turbo ion spray (TIS)/MS.[38] High performance liquid chromatography/photodiode array/mass spectrometric/evaporative light scattering detection (HPLC/PDA/MS/ELSD) allows the identification of common, less-expensive Asian *Actaea* species and *A. racemosa* in herbal samples based on the HPLC/PDA/MS/ELSD fingerprints of triterpene glycosides (cimigenol-3-O-arabinoside, cimifugin, cimifugin-3-O-glucoside).[39] Using reversed-phase HPLC with diode array detection, the limits of detection and quantitation for phenolic compounds ranged from 24.8 ± 0.15 ng/mL (caffeic acid) to 78.3 ± 0.94 ng/mL (cimicifugic acid F) and 82.7 ± 0.51 ng/mL (caffeic acid) to 260.9 ± 3.13 ng/mL (cimicifugic acid F), respectively.[6]

TREATMENT

Treatment is supportive. Although the use of black cohosh has been associated with hepatitis only in case reports, patients presenting with possible adverse reactions to black cohosh should be evaluated for hepatic toxicity.

Chapter 49

BLUE COHOSH

[*Caulophyllum thalictroides* (L.) Michx.]

HISTORY

Linnaeus originally classified blue cohosh [*Caulophyllum thalictroides* (L.) Michx.] in 1753, and subsequently André Michaux placed this plant under the genus *Caulophyllum* in 1803. Blue cohosh was a traditional medicine of Native Americans that was used as an herb to facilitate childbirth. During the 1800s, the root of this herb was used as a uterine stimulant and antispasmodic for dysmenorrhea.[1]

BOTANICAL DESCRIPTION

Blue cohosh (*Caulophyllum thalictroides*) is a native species of eastern North America along with the other North American species, *C. giganteum* (Farw.) Loconte & Blackwell. The latter species differs from *C. thalictroides* by the presence of inflorescences with a few large flowers that have large reproductive structures. The Asian member of the genus is *C. robustum* Maxim.

Common Name: Blue Cohosh, Squaw Root, Papoose Root, Blue Ginseng, Leontice, Blueberry Root

Scientific Name: *Caulophyllum thalictroides* (L.) Michx.

Botanical Family: Berberidaceae (bayberries)

Physical Description: This herbaceous, perennial, rhizomatous plant grows up to 1–2 ft (~30–60 cm) in height. The leaves are ternately or biternately compound. The yellow-green to brown flowers appear in terminal panicles. The leaves (sepals) directly underneath the flowers are large and pedal-like. The six true pedals are smaller than the sepals, and the six stamens have short filaments. The ovary of the flower is green, unilocular, and contains three ovules. The mature fruit is a dark blue berry with one to two seeds.

Distribution and Ecology: This herb grows in rich, moist woodlands of eastern North America from east of Missouri, north to southeast Manitoba and New Brunswick, and south to Alabama. The other North American species is the giant blue cohosh [*Caulophyllum giganteum* (Farw.) Loconte & Blackwell]. A closely related species (*Caulophyllum robustum* Maxim.) of *Caulophyllum thalictroides* exists in eastern Asia and Japan.

EXPOSURE

Traditional uses of the root of blue cohosh include the treatment of menstrual cramps, dysmenorrhea, epilepsy, and rheumatism. Blue cohosh is used a homeopathic remedy to enhance the progression of labor and to relieve symptoms associated with menstruation.[2] However, there is inadequate scientific evidence to support the use of blue cohosh during labor.[3] Some practitioners administer both blue cohosh and black cohosh during labor, but these herbs are not usually used during pregnancy.[4]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

PRINCIPAL INGREDIENTS

Chemical Composition

The root of blue cohosh contains a variety of alkaloids in the range of 0.02–1.1% wet weight including quinolizidine alkaloids (*N*-methylcytisine, baptifoline, anagyrine) and aporphine alkaloids (magnoflorine, aporphine) along with thalictroidine, 5,6-dehydro-alpha-isolupanine, alpha-isolupanine, lupanine, taspine, and sparteine.[5,6] Based on three samples of roots/rhizomes of blue cohosh, magnoflorine is the major alkaloid (0.5–0.7 g/100 g dry weight) with the mean concentration of *N*-methylcytisine ranging from about 0.01–0.4 g/100 g dry weight.[7] The concentration of individual alkaloids in root extracts ranges from approximately 0.02–1.1% wet weight. Analysis of an ethanol extract of blue cohosh demonstrated relative high concentrations of magnoflorine (11 mg/g dry weight) followed by *N*-methylcytisine (0.9 mg/g dry weight), baptifoline (0.75 mg/dry weight), and anagyrine (0.18 mg/g dry weight).[8] Figure 49.1 displays the chemical structures of the major alkaloids and triterpene saponins in blue cohosh. There are at least seven triterpene saponins in the root of blue cohosh including caulosaponin [caulosapogenin, $C_{42}H_{62}O_2(OH)_4$, and dextrose] and caulophyllosaponin (hederagenin, $C_{30}H_{48}O_4$, and arabinose).[9]

Copyright John Wiley & Sons Limited.

Physiochemical Properties

In vitro studies in the early 1940s suggested that alcohol extracts of blue cohosh root contain glycosides with uterine stimulant and coronary vasoconstrictive properties.[10] In the rat embryo culture, the quinolizidine alkaloid, *N*-methylcytisine, exhibits teratogenic activity,[6] similar to other quinolizidine alkaloids.[11] However, thalictroidine, anagyrine, and alpha-isolupanine were not teratogenic at the tested concentrations, and taspine demonstrated high embryotoxicity, but no teratogenic activity. In animal models, *N*-methylcytisine exhibits mild nicotinic activity.

Mechanism of Toxicity

The toxic constituents in extracts of blue cohosh have not been determined; therefore, the mechanism of toxicity is unknown. To date, toxic effects of blue cohosh have been described in case reports and there is no consistent pattern of toxicity. The trauma associated with the use of this extract to induce illicit abortions could potentially cause sepsis.

DOSE RESPONSE

Typically, blue cohosh is consumed as a decoction (e.g., one teaspoon of dried root in cup of water brought to a boil and simmered for 10 minutes). However, because of safety issues and the lack of efficacy, this herb is not usually recommended during pregnancy.

TOXICOKINETICS

There are few human data on the toxicokinetics of components derived from blue cohosh.

CLINICAL RESPONSE

Acute Effects

A 21-year-old woman developed a nicotine-like intoxication (tachycardia, diaphoresis, abdominal pain, vomiting, muscle weakness, abdominal wall fasciculations) following the ingestion of blue cohosh (*Caulophyllum thalictroides*) for 4 consecutive days (10–20 doses/daily) as an abortifacient.[12] These symptoms were consistent with the nicotinic effects of *N*-methylcytisine present in

blue cohosh. In addition to the blue cohosh, she ingested 15 cups of slippery elm (*Ulmus rubra* Muhl.) tea daily for 4 days and used slippery elm douches. Similar nicotinic effects have not been reported following the ingestion of slippery elm tea.

Chronic Effects

A case report associated the development of cardiomegaly, pulmonary edema, and profound hypokinesis of the left ventricular posterior wall of a newborn with the ingestion of three times the recommended dose of blue cohosh during the month before delivery.[13] An alternate explanation (e.g., congenital coronary artery anomaly, viral infection) could not be confirmed. At 2-year follow-up, the child was developing normally, but cardiomegaly and mild reduction in left ventricular function remained.

DIAGNOSTIC TESTING

Methods for the detection of alkaloids and triterpene saponins in blue cohosh include high performance liquid chromatography and evaporative light scattering detection.[7]

TREATMENT

Treatment is supportive.

Chapter 50

BORAGE

(*Borago officinalis* L.)

BOTANICAL DESCRIPTION

The large, deep green, leaves of common borage are covered with white, stiff, prickly hairs, and occasionally the leaves of borage may be confused with the large, fussy, deep green leaves of foxglove. Misidentification of foxglove for borage resulted in digitoxin poisoning after the patient ingested a brewed tea from the misidentified foxglove leaves.[1]

Common Name: Common Borage, Bee Plant, Bee Bread, Ox's Tongue

Scientific Name: *Borago officinalis* L.

Botanical Family: Boraginaceae (borage, bourraches)

Physical Description: This hairy, annual herb grows up to 2–3 ft (~60–90 cm) in height. The leaves are alternate, wrinkled, oval, and pointed with dimensions of about 1.5 by 3 in (~4 cm by 8 cm). Bright blue to pink, star-shaped flowers appear in loose racemes during the summer. Borage has a salty flavor with an aroma of cucumbers.

Distribution and Ecology: This plant inhabits wide areas of the west coast and the northern and northeastern states of the United States, as well as southern Europe. Although this plant is native to Syria, common borage has naturalized in the warmer parts of central, eastern, and western Europe. The common name, bee plant, is derived from the use of this plant as an attractant for honeybees.

EXPOSURE

Sources

The leaves of borage are used raw in salads, steamed as a tea, or cooked in vinegar as a vegetable. Common borage is widely cultivated as an ornamental plant and as a pot herb

Medicinal Uses

TRADITIONAL

Borage oil (starflower oil) is an alternative to evening primrose as a source of γ-linolenic acid. Traditional herbal uses for borage include the treatment of arthritis, chest congestion with or without cough, inflammation, sore throat, depression, seborrheic dermatitis, and menopausal symptoms. Borage oil is a supplement increasing used by older patients for the treatment of premenstrual syndrome, diabetes, skin disorders, and rheumatoid arthritis.[2] Borage oil is a traditional treatment for a hangover.[3]

CURRENT

The decreased production of anti-inflammatory dihomo-γ-linolenic acid metabolites (e.g., prostaglandin E_1, 15-hydroxyeicosatrienoic acid) in patients with atopic dermatitis suggests a role for γ-linolenic acid in the treatment of this disorder. The amount of γ-linolenic is

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

substantially higher in borage oil than in evening primrose oil (i.e., about 23–25% vs. 8–10%, respectively). Studies on atopic dermatitis following the use of evening primrose yield conflicting results.[4] One hundred sixty patients with stable, moderate disease activity of atopic dermatitis were randomized to a treatment group (500 mg borage oil capsules) and to placebo (bland lipid miglyol) over 24 weeks.[5] Although several clinical symptoms (erythema, vesiculation, excoriation, lichenification, insomnia) improved in the treatment group compared with placebo, the overall response to borage oil did not reach statistical significance as measured by the amount of topical corticosteroid used and clinical symptoms (Costa score). However, there was some improvement in the subgroup of the treatment group that included patients with documented compliance and increased erythrocyte dihomo-γ-linolenic acid. A similar borage oil-induced reduction is postulated for the elevation of tumor necrosis factor-α associated with rheumatoid arthritis,[6,7] but there are inadequate clinical data to support the routine use of borage oil supplements for the treatment of rheumatoid arthritis. A randomized, double-blind, placebo-controlled, 24-week trial of 37 patients with rheumatoid arthritis and active synovitis suggested that daily treatment with 1.4 g γ-linolenic acid in borage seed oil improved the symptoms and signs of rheumatoid arthritis.[8]

Regulatory Status

Borage oil is a dietary supplement in the United States. The German Commission E does not approve the use of borage oil because of concerns about potential hepatic and carcinogenic effects of the pyrrolizidine alkaloids in borage oil.

PRINCIPAL INGREDIENTS

Constituents of borage oil (CAS RN: 225234-12-8) include acids (acetic, lactic, malic silicic), alkaloids, fatty acids (γ-linolenic acid, linoleic acid, oleic acid, saturated fatty acids), mucilages, tannins, and saponins. Linoleic, linolenic, and oleic acids comprise about 75% of the total fatty acids in borage oil.[9] γ-Linolenic acid is an essential ω-6 polyunsaturated fatty acid that also occurs in evening primrose (*Oenothera biennis* L.) and black currant seed (*Ribes nigrum* L.). This compound is one of at least 79 triacylglycerols present in borage oil as measured by silver-ion high-performance liquid chromatography (HPLC)/atmospheric pressure chemical ionization/mass spectrometry.[10] In addition, borage oil contains small amounts (<10 ppm dry weight leaves) of pyrrolizidine alkaloids (e.g., amabiline, intermedine, lycopsamine, supinine), which are potentially hepatotoxic. As a result of the presence of pyrrolizidine alkaloids, the German Federal Health Agency limits the consumption of unsaturated pyrrolizidine alkaloids to ≤1 µg daily. Borage oils products are certified as being free of unsaturated pyrrolizidine alkaloids when the unsaturated pyrrolizidine alkaloid content is ≤0.5–1 µg/g.

DOSE RESPONSE

Clinical trials suggest that borage oil is a relatively safe dietary supplement in daily doses of 500–720 mg. In these studies, daily doses of borage oil administered as 500-mg borage capsules[5] or 720-mg γ-linoleic acid in gelatin capsules[11] were well tolerated.

TOXICOKINETICS

In vitro studies indicate that neutrophils rapidly elongate γ-linolenic acid by two carbons to dihomo-γ-linolenic acid (DGLA) following the use of borage oil as a dietary supplement.[12] Subsequently, biotransformation of DGLA by 15-lipoxygenase results in the formation of 15-hydroxy-eicosa-trienoic acid.[13]

Theoretically, the ingestion of borage oil may lower the seizure threshold based on the development of seizures with evening primrose oil, which contains 8–10% γ-linolenic acid.[14] However, there are no well-documented case reports associating the use of borage oil with seizures.

CLINICAL RESPONSE

In a study of 80 patients treated with 500 mg borage oil daily for 24 weeks, there were no definite herb-related adverse effects. One patient was withdrawn from the study for headache, diarrhea, and vomiting, but these effects could not be causally linked to borage oil. There are few data including case reports on the toxicity of borage or borage oil. A case report associated the development of atrial fibrillation, bradycardia, and gastrointestinal distress in a 72-year-old woman, who drank tea from leaves that she thought were borage.[1] Subsequent laboratory analysis indicated that she confused borage leaves for foxglove, and thus she probably had digitoxin poisoning.

DIAGNOSTIC TESTING

Methods for the detection of α- and γ-linolenic acid moieties include silver-ion HPLC followed by online atmospheric pressure chemical ionization/mass spectrometry (APCI/MS). HPLC/APCI/MS identified 79

triacylglycerols in borage oil derived from *Borago officinalis* seeds.[15]

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary.

Chapter 51

BURDOCK ROOT
(*Arctium lappa* L.)

HISTORY

The burdock root has been used since antiquity as a treatment for diabetes, venereal diseases, and skin lesions.

BOTANICAL DESCRIPTION

Common Name: Burdock, Gobo, Great Burdock, Greater Burdock

Scientific Name: *Arctium lappa* L.

Botanical Family: Compositae (Asteraceae)

Physical Description: Burdock is a tall biennial plant that grows in open areas as an introduced weed. Round pink-purple flowers appear during the second year. These flowers contain sharp spines (hooklets) that resemble thistle and develop into tenacious burrs. This plant has a large tap root.

Distribution and Ecology: This herb grows throughout the United States as an introduced annual weed. *Arctium* species are native plants in Europe and Asia.

EXPOSURE

Burdock is a popular edible vegetable in Japan called gobo, which contains a variety of fructans.[1] Traditional uses include the treatment of acne, psoriasis, venereal diseases, rheumatism, scurvy, whooping cough, conditions that require diuresis, and colds.[2] The tea brewed from burdock is a coffee and traditional tea substitute. Burdock is a constituent of some scalp and hair preparations as well as moisturizing creams. There are few data on the clinical efficacy of preparations containing burdock.

PRINCIPAL INGREDIENTS

Chemical Composition

Lignans are plant products of low molecular weight formed primarily from oxidative coupling of two *p*-propylphenol moieties (i.e., two C_6C_3 units) at their β-carbon atoms, whereas neolignans are plant products with units coupled in other ways. These lignans have a variety of biological activities. The seeds of *A. lappa* contain several dibenzylbutyrolactone lignans including arctigenin (MW 372, CAS RN: 7770-78-7) and the associated 4-glucoside, arctiin (MW 534, CAS RN: 20362-31-6) along with smaller concentrations of matairesinol, secoisolariciresinol, and neoarctin B.[3] The concentrations of these lignans varies between different plant parts. In a study of the stereochemistry of lignan biosynthesis in *Arctium lappa*, the seeds contained significant amounts of matairesinol and arctigenin compared with secoisolariciresinol, whereas the petioles contained only small amounts of secoisolariciresinol and no detectable concentrations of matairesinol and arctigenin.[4] The enantiomers of the secoisolariciresinol in the seeds and petioles were opposite to each other. Burdock root contains volatile oils, fatty oils, sucrose, resin, tannin, and inulin, but there are no significant amounts of atropine-like alkaloids. Figure 51.1 displays the chemical

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

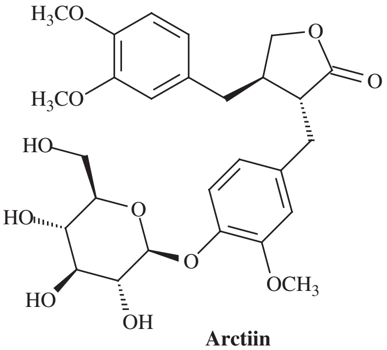
Arctigenin



Arctiin

FIGURE 51.1. Chemical structures of arctigenin ($C_{21}H_{24}O_6$), and arctiin (arctigenin-4-glucoside, $C_{27}H_{34}O_{11}$).

structures of arctigenin and arctiin, the two major lignans in burdock seeds. Analysis of the commercial preparations of burdock root from case reports associated with toxicity demonstrated the presence of atropine at concentrations of 0.76 mg/g and 30 mg/g, probably as a contaminant.[5,6]

Physiochemical Properties

Lignans are present in almost all plants, and these compounds demonstrate a wide variety of biological responses. In many plants, arctigenin is a precursor in the synthesis of catechols.

DOSE RESPONSE

Use of burdock root involves drinking a decoction three times daily that is made by steeping one teaspoonful of the root into a cup of boiling water and simmering for 10–15 minutes. About 2–4 mL of the tincture is ingested three times daily. A toxic dose of burdock root extract has not been well defined because of a lack of human data.

TOXICOKINETICS

In vitro studies indicate that the lignan, arctiin, undergoes cleavage of the glycosidic bond to form the aglycone, arctigenin.[7] Further demethylation of arctigenin in the rat intestine at the 3″-position produces a secondary metabolite, 2-(3″, 4″-dihydroxybenzyl)-3-(3′, 4′-dimethoxyl)-butyrolactone.

CLINICAL RESPONSE

Several cases of mild anticholinergic poisoning (dizziness, dry mouth, blurred vision, mydriasis, weakness, urinary retention, confusion) developed after consumption of teas brewed from burdock root.[5] Analysis of the tea associated with these cases suggested that atropine contaminated the teas, but the source of this contamination was unclear. A case report associated the application of burdock root as a plaster for joint injuries with contact dermatitis (erythema, pruritus, exudation).[8] Patch tests for burdock were positive in these patients. Another case report associated the development of anaphylaxis (hypotension, diffuse erythema, stridor with the consumption of boiled burdock root.[9]

The burrs from the seed pod cause mechanical injuries. Case reports associate a conjunctival foreign body reaction (conjunctival erythema, tearing) and multiple, fine, linear corneal abrasions with embedded burdock spines in the palpebral conjunctiva.[10] The unbroken shaft from these spines is only 1 mm (~.04 in.) in length; therefore, slit lamp examination is required to identify the presence of these small foreign bodies in the palpebral conjunctiva. Serious secondary infections may develop characterized by chemosis and lid edema.[11] The ingestion of boiled burdock has been associated with the development of anaphylactic shock.[12]

DIAGNOSTIC TESTING

Analytical methods for determining the presence of lignans (arctiin, arctigenin) in commercial samples of burdock (*Arctium lappa*) include polyamide column chromatography with detection by high performance liquid chromatography/electrospray ionization mass spectrometry (HPLC/ESI/MS)[13] and reverse phase HPLC with photodiode array detection (280 nm).[14] The limits of detection and quantitation for the latter method were 1.22 ng and 3.69 ng, respectively.

TREATMENT

Treatment is supportive. Hypersensitivity reactions can develop following exposure to burdock root including anaphylactic reactions; therefore, patients should be evaluated for the presence of angioedema, wheezing, stridor, and hypotension associated with severe allergic reactions. Eye injuries should be evaluated by slit lamp examination for the presence of retained foreign body.

Chapter 52

CALAMUS
(*Acorus calamus* L.)

HISTORY

Calamus has been used as a sedative, antipyretic, and antispasmodic since biblical times. This herb was introduced to Eastern Europe from Central Asia as a medicinal plant in the 16th century.[1] Historical uses of calamus include a spice for cooking, a flavoring for tooth powders and tonics, and an additive in pharmaceuticals and foods for taste and aroma. North American Indians used pulverized calamus root as snuff for the treatment of upper respiratory tract infections and as a stimulant for horses.[2] In colonial times, the fragrant oils were constituents of sacred oils and alcoholic beverages;[3] the aromatic leaves were popular room deodorizers and insect repellants. In 1974, the US Food & Drug Administration (FDA) banned the use of *Acorus calamus* as a result of animal studies demonstrating carcinogenic effects following chronic oral administration of this herb. These studies used the Jammu (Indian) variety of calamus oil, which contains about 80% β-asarone, rather than the European variety that contains much lower concentrations of β-asarone. However, the ban included all oils of calamus because of the lack of scientific data demonstrating the safety of the European or Kashmir varieties.[4]

BOTANICAL DESCRIPTION

In addition to *Acorus calamus* (calamus), plant species containing the flavoring agent, β-asarone, include *Acorus europaeum* L. (hazelwort).

Common Name: Calamus (Sweet Flag, Sweet Myrtle, Sweet Root, Sweet Sedge, Rat Root)

Scientific Name: *Acorus calamus* L.

Botanical Family: Acoraceae (formally under Araceae and genus *Arum*)

Physical Description: This perennial herbaceous monocot has branched, aromatic horizontal rhizomes that extend up to or near the soil surface. The leaves are erect with a cross-section in the shape of a rhomboid and veins along the whole length the leaf. These leaves are not differentiated into petiole and blade. The flowers are perfect and regular with six concave perianth segments. There are six stamens and 2–3 carpels, and a superior ovary with 2–3 locules. The mature fruit is hard and dry with a pyramid-shape (obpyramidal) that has an attachment near the narrow end.

Distribution and Ecology: Calamus is a semi-aquatic, aromatic herb, which inhabits moist areas near swamps, ponds, and streams in Asia, Europe, and North America at altitudes of 3,000–6,000 ft (~1,000–2,000 m).

EXPOSURE

Sources

Calamus oil is a flavoring additive to beer, distilled beverages (vermouth, liqueurs, bitters), and some food products (cakes, frozen desserts, yogurts) and drugs. Based on limited data, the maximum daily intake of

β-asarone from the use of calamus oil in these products is approximately 2 μg/kg body weight.[5]

Medicinal Uses

Traditional

Calamus is a traditional Ayurvedic medicine in India, particularly for psychiatric disorders (depression, insomnia, anxiety, psychosis) and epilepsy.[6] Traditional Chinese medicine uses asarum oil (*Asarum sieboldii* Miquel, *Asarum heterotropoides* F. Schmidt), which contains substantial amounts of α-asarone and smaller amounts of the more toxic β-asarone, include the treatment of fever, pain, infection, and sedation.[7]

Current

Calamus is a common Ayurvedic medicine in India, but the distribution of this herb in the United States is limited. The fragrant oils from calamus rhizomes remain constituents of potpourri, perfume, and sacred oils.

Regulatory Status

The FDA banned the use of calamus as a flavoring agent in beverages, pharmaceuticals, and dental preparations because of the animal studies suggesting that β-asarone was carcinogenic following chronic oral administration. The presence of β-asarone in food is also not authorized in Canada. The European Council (Annex II of Directive 88/388/ECC) limits the β-asarone content in nonalcoholic and alcoholic beverages to 0.1 mg/kg and 1 mg/kg, respectively.[8]

PRINCIPAL INGREDIENTS

Chemical Composition

The essential oils of calamus (CAS RN: 8015-79-0) are mixtures of terpene and/or phenylpropanoic derivatives, and the composition of the essential oil from the rhizomes of *A. calamus* depends on the cytotypes. Karyological analysis of *Calamus* species indicates that these plants have four cytotypes (karyotypes): diploid (2x = 24), triploid (3x = 36), tetraploid (4x = 48), and hexaploid (6x = 72). The concentration of the carcinogen (i.e., β-asarone) depends on the cytotype; separation of the cytotypes of this species requires the chromosomal analysis rather than determination of anatomical characteristics. α- and β-Asarone are major components of triploid and tetraploid plants from calamus plants in the Old World, but the diploid calamus plants from the New World do not contain significant amounts of the carcinogenic compound, β-asarone. European and North American triploid cytotypes contain 3–19% β-asarone, whereas the Indian, Indonesian, and Taiwanese tetraploid cytotypes contain up to 96% β-asarone.[9] As measured by capillary electrophoresis, the β-asarone content of a diploid rhizome of *A. calamus* from the wetlands of the Midwestern United States was 0.2% wet weight compared with 4.4% wet weight for a commercial product derived from a triploid variety from India.[10] Analysis of alcoholic extracts of the triploid *A. calamus* by gas chromatography/mass spectrometry (GC/MS) demonstrated the following constituents: β-asarone (11%), α-selinene (5.02%), E-β-ocimene (3.28%), camphene (2.27%), τ-cadinol (2.00%), camphor (1.54%), and calarene (1.42%). The diploid specimen of *A. calamus* contained no detectable amounts of β-asarone as well as higher concentrations of acorone (26.33%), preiso calamendiol (22.81%), iso-shyobunone (8.62%), and β-sesquiphellandrene (3.28%), when compared with triploid specimens.[9] In an analytical study of Romanian oil of calamus and an alcoholic extract of Romanian *A. calamus*, the concentrations of α-asarone were 5.2–6.7 μg/mL and 2.7–5.7 μg/mL, respectively, and the concentration of β-asarone were 91–98 μg/mL and 88–97 μg/mL, respectively.[11] The essential oil of *Asarum europaeum* L. (European wild ginger) also contains substantial amounts of α-asarone and much smaller amounts of the more toxic β-asarone.[12] As measured by GC/MS, the content of α-asarone and β-asarone in essential oils from the steam distillation of *Asarum europaeum* rhizomes was 460–510 μg/mL and 24–29 μg/mL, respectively.[11]

Physiochemical Properties

The two geometrical isomers of the alkenylbenzene compound, asarone (CAS RN: 494-40-6), are α-asarone [*trans*-1,2,4-trimethoxy-5-(1-propenyl) benzene, CAS RN: 2883-98-9] and β-asarone [*cis*-1,2,4-trimethoxy-5-(1-propenyl) benzene, CAS RN: 5273-86-9]. Figure 52.1 demonstrates the chemical structures of α- and β-asarone. In animal studies, α-asarone and β-asarone potentiate the sedative properties of barbiturates and ethanol with the effects of β-asarone being much stronger than α-asarone.[13,14]

Mechanism of Toxicity

In a 2-year study, rats were fed 0, 500 ppm, 1000 ppm, 2,500 ppm and 5,000 ppm of oil of calamus (Jammu variety).[15] Dose-related toxic effects included moderate to marked growth retardation and degenerative changes in the liver and heart. Malignant tumors developed in the duodenum of rats at all oil of calamus dosages beginning in the 59th week of dosing.

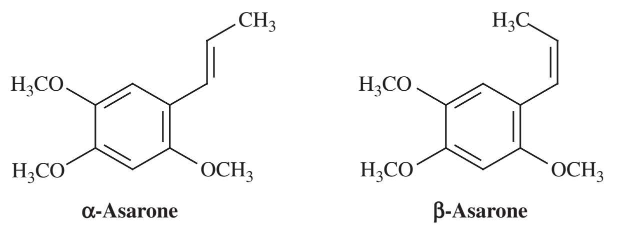

FIGURE 52.1. Chemical structures of α-asarone and β-asarone.

DOSE RESPONSE

There are inadequate data to determine the toxic dose of calamus oil or calamus root. Large amounts of the root (45–350 mg) are ingested in the belief that hallucinations will occur as a result of the biotransformation of β-asarone to a derivative of the hallucinogen, trimethoxyamphetamine (TMA). However, there are inadequate data to associate specific doses with gastrointestinal or psychedelic effects, particularly because of the variable amount of asarone in calamus oil and in the root.

TOXICOKINETICS

There are few data on the human toxicokinetics of α- or β-asarone. In rodent studies, the intragastric administration of β-asarone results in the rapid absorption and elimination of this compound with a peak concentrations occurring within about 15 minutes.[16] The serum elimination half-life of β-asarone was approximately 1 hour.

CLINICAL RESPONSE

The ingestion of 8 in. (~20 cm) of *Acorus calamus* rhizome with water by a 19-year-old man produced gastrointestinal irritation, manifest by vomiting and diaphoresis.[17] The patient recovered within several hours without sequelae after supportive care. β-Asarone is an animal carcinogen based on limited animal studies, but there are no human data to confirm the carcinogenic potential of this constituent of oil of calamus. This compound has genotoxic and mutagenic properties in *in vitro* assays. In hepatocytes, β-asarone induces unscheduled DNA synthesis,[18] and commercial drugs containing β-asarone are mutagenic in a *Salmonella*/mammalian-microsome assay.[19]

DIAGNOSTIC TESTING

Analytical methods to determine the presence of α- and β-asarone include thin-layer chromatography (TLC) coupled with either UV-Vis absorbance or fluorescence detection,[11] high performance TLC,[20] high performance liquid chromatography (HPLC),[21,22] and gas chromatography/mass spectrometry.[23] TLC methods lack reproducibility and do not easily distinguish isomer content. Micellar electrokinetic capillary chromatography UV Vis absorbance is a rapid and inexpensive method for the determination of β-asarone content of natural products after simple alcohol extraction.[10]

TREATMENT

Treatment of acute exposure to *Acorus calamus* is supportive, primarily involving the replacement of fluid and correcting electrolyte imbalance as needed.

Chapter 53

CAMPHOR
(*Cinnamomum camphora* T. Nees & Eberm.)

HISTORY

In China, camphor has been used for centuries as an antiseptic, antipruritic, cold remedy, and abortifacient. *Linimentum camphoratum* was officially recognized as medicinal product in the first edition of the *US Pharmacopeia*, published in 1820. Up until the 1930s, camphor was used as a circulatory stimulant and analeptic. Reports on camphor toxicity were first reported in the English medical literature in the late 19th century.[1] Gastrointestinal irritation, seizures and altered consciousness were well-recognized complications of acute camphor poisoning in the early 20th century.[2] By 1954, over 130 cases of camphor poisoning had been reported in the medical literature, primarily involving the accidental ingestion of camphorated oil or camphor-containing cough and cold preparations.[3] These reports included approximately 20 deaths attributed to camphor intoxication.[4] In 1982, the US Food & Drug Administration (FDA) declared camphorated oil as "not generally recognized as safe," and the concentration of camphor in US over-the-counter products was limited to <11%. Camphor is no longer listed in the *US Pharmacopeia* or the National Formulary.

BOTANICAL DESCRIPTION

Common Name: Camphor Tree, Camphor Laurel

Scientific Name: *Cinnamomum camphora* T. Nees & Eberm. (*Camphora camphora* Karst., *Laurus camphora* L.)

Botanical Family: Lauraceae (laurel family)

Physical Description: The camphor tree is a broad-leafed evergreen in topical and subtropical regions of the world that grows to 50–100 ft (~15–30 m) in height. Young branches are green with tinges of red. The tops of the leaves are shiny with three distinct veins, whereas the underneath side of the leaves are somewhat pale. Crushing the leaves produces an aromatic odor. The flowers are yellow-white, borne in small inflorescences. The fruits are round, pea-sized berries attached to the branchlets by small, cup-like green cones. The immature fruits first turn red, and then turn black during maturation. The fruits contain a single seed.

Distribution and Ecology: This plant is indigenous to Taiwan, China, and Japan, but camphor is widely cultivated in subtropical regions of the world.

EXPOSURE

Sources

The traditional source of camphor is the wood of *Cinnamomum camphora*, an evergreen tree native to eastern Asia. Camphor from natural sources is the dextrorotatory isomer. Currently, the primary source of camphor is the steam distillation and crystallization of pinene, which is converted to camphene by treatment with acetic acid and nitrobenzene.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Medicinal Uses

Traditional

Traditional uses of camphor include administration as an antiseptic, antipruritic, rubefacient, mild anesthetic, abortifacient, contraceptive, inhalant for cold preparations, and suppression of lactation. Rarely, this compound has been used as a homicidal or suicidal agent.

Current

The use of camphor is limited to inhalation of vaporized solutions and dermal application of topical compounds. Camphor is used as a rubefacient/liniment (0.1–3%), a constituent of embalming fluid, and a dental antiseptic (65% camphor, 35% parachlorophenol) for root canals. Frequently, dermal products containing camphor also contain other potentially toxic ingredients (phenol, eucalyptus oil, menthol). Topical products containing camphor include Campho-Phenique® antiseptic gel (10.8% camphor and 4.7% phenol; Bayer Consumer Products, Morristown, NJ) and Vicks Vaporub® (5% camphor, 5% turpentine oil, 2.75% levomenthol, 1.5% eucalyptus oil; Procter & Gamble Consumer Products, Cincinnati, OH). Commercial products that may contain camphor include lacquers, varnishes, plasticizers for cellulose esters and ethers, moth repellents, explosives and pyrotechnics, and preservatives for pharmaceuticals and cosmetics.

Regulatory Status

Camphorated oil typically contained 20% camphor weight/volume (w/v) in cottonseed oil. However, in 1982, the FDA banned the sale of over-the-counter products containing this concentration of camphor due to serious central nervous system (CNS) toxicity following accidental ingestion.[5] Camphor now appears in US over-the-counter topical preparations in concentrations ranging up to 11%.[6]

PRINCIPAL INGREDIENTS

Chemical Composition

Camphor (CAS RN: 76-22-2) is a cyclic ketone of the hydroaromatic terpene group. Figure 53.1 displays the chemical structure of this compound ($C_{10}H_{16}O$). Twenty grams of Vicks Vaporub® (i.e., about 5% camphor) contains about 1g of camphor, whereas 10mL of Campho-Phenique® (i.e., about 10.8% camphor) contains about 1g of camphor. Oxygenated monoterpene compounds were the major ingredients of the headspace constituents of a fresh sample of a Japanese specimen of *C. camphora* with camphor and 1,8 cineole accounting for 70% and 7.5% of the total, respectively.[7] The sample also contained about 8% monoterpenes (camphene, α-pinene, limonene) and approximately 9% sesquiterpene hydrocarbons. Cinnamomin is a ribosome-inactivating protein (RIP) isolated from mature seeds of the camphor tree that belongs to the type II class of RIPs.[8] These toxic proteins consist of an A-chain with RNA *N*-glycosidase activity and a galactose-specific lectin B-chain. The seeds of *Cinnamomum camphora* also contain a type I RIP, camphorin, with a molecular mass of 23kDa.[9] These ribosome-inactivating proteins consist of a single peptide chain with a molecular mass between 25–30kD.

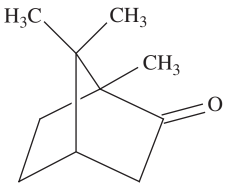

FIGURE 53.1. Chemical structure of camphor.

TABLE 53.1. Physiochemical Properties of Camphor

Physical Property	Value
Melting Point	180°C/356°F
Boiling Point	204°C/399°F
log P (Octanol-Water)	2.38
Water Solubility	1600mg/L (25°C/77°F)
Vapor Pressure	0.65mmHg (25°C/77°F)
Henry's Law Constant	8.10E-05 atm-m^3/mole (25°C/77°F)
Atmospheric OH Rate Constant	9.88E-12cm^3/molecule-second (25°C/77°F)

Physiochemical Properties

Camphor is a translucent, crystalline solid at room temperature with a penetrating characteristic odor and a pungent, aromatic taste. Table 53.1 lists some of the physiochemical properties of camphor. Cinnamomin is a type II ribosome-inactivating protein, similar to other heterodimeric proteins (e.g., ricin) in this class. These 61kD-proteins inhibit protein synthesis by acting as a RNA *N*-glycosidase to remove an adenine at A4324 in the sarcin/ricin domain (S/R domain) of the largest RNA in the 28S ribosome.[10] This domain is responsible for the interaction of elongation factors with ribosomes. Although cinnamomin A-chain inhibits protein synthesis similar to ricin, *in vitro* studies in BA/F3β cells

indicate that the cytotoxicity of cinnamomin is substantially lower than ricin.[8]

Mechanism of Toxicity

Following ingestion, camphor produces dose-dependent CNS excitation and gastrointestinal (GI) irritation. There are limited data on the toxic compounds in camphor, and the specific toxins (i.e., parent compound or toxic alcohol metabolite) in camphor that cause these CNS and GI effects remains unknown. Although cinnamomin is a type II ribosome-inactivating protein structurally and functionally similar to ricin, abrin, viscumin, ebulin 1, and nigrin b, the role of this protein in producing human toxicity remains undefined. Volunteer studies suggest that short-term exposure to vapors containing camphor stimulate cold receptors in the nose, but these vapors do not alter air flow through the nasal passages.[11]

DOSE RESPONSE

The ingestion of ≥1 g (5 mL of a 20% camphor solution) camphor by a child is a serious intoxication.[12] Camphor toxicity is unlikely to develop following the ingestion of ≤10 mg camphor/kg based a retrospective review of poison center data and the medical literature.[13] In a study from the 1920s of 80 postpartum women receiving camphor injections into engorged breasts, one women developed adverse reactions (nausea, vomiting) attributed to the treatment.[14] Adverse reactions were not reported for the rest of the subjects. The camphor regimen involved 195 mg camphor the first day, followed by three daily injections of 97 mg for a total camphor dose of 486 mg. Although minor GI symptoms may develop following the ingestion of 30–50 mg/kg, serious toxicity including convulsions is uncommon. The ingestion of 6–10 g camphor as a stimulant by two adults resulted in anxiety, agitation, and depersonalization.[15] There were no seizures. Major toxicity occurs following the consumption of camphor doses exceeding 150 mg/kg from preparations containing 20% camphor in cottonseed oil or camphor spirts (10% camphor in ethanol or isopropyl alcohol). The intentional ingestion of 68 mg camphor/kg (44 mL Campho-Phenique® – 10.8% camphor) by a 20-year-old man caused the onset of seizures within 10 minutes followed by vomiting and coma requiring intubation and respiratory support.[16] The patient recovered without sequelae within 24 hours. Another adult survived the ingestion of 42 g camphor with basic supportive care.[2] A survey of a camphor packaging facility indicated that exposure to ambient air concentrations exceeding 2 mg camphor/m^3 (2 ppm) causes mild to moderate eye, nose, and throat irritation.[17]

TOXICOKINETICS

Absorption

The absorption of camphor from the GI tract is relatively rapid based on limited data from volunteer studies and case reports. Seizures can develop within 5–10 minutes of the ingestion of camphor.[18] In fasted rats receiving one gram camphor as a 40% concentration of camphorated oil dissolved in cottonseed oil, the peak camphor concentration occurred about $1\frac{1}{2}$ hours after oral gavage.[19] The presence of food in the stomach delays absorption of camphor from the GI tract. Volunteer studies suggest that the systemic absorption of camphor from the skin is relatively low.[20]

Distribution

Camphor is highly tissue bound with a volume of distribution of approximately 2–4 L/kg.[21] This compound is widely distributed after absorption including diffusion into amniotic fluid, fetus, brain, liver, and kidney.

Biotransformation/Elimination

Based on animal studies, the biotransformation of camphor involves the oxidation of camphor to campherols (2-hydroxycamphor, 3-hydroxycamphor, borneol) followed by conjugation of these alcohols with glucuronic acid.[22] These inactive glucuronide conjugates are excreted in the urine. Analysis of urine following the ingestion of camphor as a stimulant by two adults demonstrated hydroxylated metabolites (3-OH-, 5-OH-, 8-OH-, 9-OH-camphor), which subsequently underwent oxidation to the corresponding ketone and carbonic acid with the latter compounds excreted as a glucuronides.[15] Very small amounts of unchanged camphor appear in the urine after absorption. The plasma elimination half-life of camphor following oral administration of 200 mg camphor to two volunteers was approximately 1.5 and 2.5 hours.[21] The mean elimination serum half-life of camphor was approximately 2 hours in a group of 50 rats receiving one gram camphor as a 40% concentration of camphorated oil dissolved in cottonseed oil.[19] The lungs excrete small amounts of camphor, resulting in the characteristic pungent odor of exhaled breath.

CLINICAL RESPONSE

Acute Effects

The primary effects of camphor intoxication are gastrointestinal irritation, seizures, and CNS depression. As a

result of the rapid absorption of camphor, clinical effects begin soon (i.e., about 5–90 minutes) after ingestion.[23,24] The first symptoms of camphor intoxication occurred about 45 minutes after accidental ingestion of $1\text{–}1\frac{1}{2}$ tablespoons of camphorated oil by a group of children (age 4–10 years).[25] Initially, local irritation of the GI tract occurred following ingestion, manifest by pain in the mouth and throat, nausea, vomiting, and a nonspecific feeling of warmth. Spontaneous nausea and vomiting occur in most patients ingesting more than a small amount of camphor. Other clinical features of camphor intoxication include headache, lightheadedness, anxiety, agitation, confusion, hallucinations, hyperreflexia, and myoclonus.[15,21,26] Toxicity following dermal application or inhalation is not usually associated with GI symptoms.[27] The odor of camphor may be present in the breath, vomitus, or urine, but the absence of this odor does not exclude camphor toxicity. Serious CNS effects include headache, confusion, vertigo, restlessness, delirium, hallucination, and muscle jerks that progress to tonic-clonic seizures.[28] Life-threatening effects include status epilepticus, coma, apnea, and pulmonary aspiration. Camphor is a local irritant of the eye and upper respiratory tract. Death from acute camphor ingestion is uncommon today,[29,30] but potentially fatal complications involve respiratory failure from status epilepticus or aspiration pneumonia. Symptoms usually resolve within 24 hours without sequelae.

Chronic Effects

Case reports have not associated camphor poisoning during pregnancy with teratogenesis or adverse neonatal effects. Serious camphor intoxication in a 32-year-old woman during the first trimester of pregnancy resulted in several seizures and altered consciousness.[31] Six months later she delivered a normal infant. Camphor is highly lipophilic, and this compound can cross the placenta. Although a neonatal death occurred shortly after the mother demonstrated signs of camphor poisoning, the role of camphor in the death of the child was unclear.[32] A 26-year-old mother with a history of preeclampsia delivered a normal infant one day after she demonstrated the effects of camphor intoxication (agitation, hyperreflexia, tremor, seizure, nausea, lethargy) following the accidental ingestion of 12 g camphorated oil.[33]

Authors have associated mild elevation of serum hepatic aminotransferases with the use of topical compounds containing camphor, but the contribution of camphor to these changes remains unclear.[34] A case report associated the development of acute hepatic encephalopathy (prodromal viral syndrome, diffuse interstitial infiltrates, rapid neurological deterioration, hypoglycemia, hepatomegaly) with the chronic administration of a home remedy containing camphor and whiskey to a 6-month child over 5 months.[35] Although certain features of this illness simulated Reye's syndrome, the liver histology did not demonstrate the pleomorphic, swollen mitochondria and loss of dense intramitochondrial bodies usually seen in fatal cases of Reye's syndrome.

DIAGNOSTIC TESTING

Analytical Methods

Near-infrared (NIR) technology is a sophisticated analytical method for the quality control of camphor-containing products that allows the rapid identification of individual components and the detection of adulteration.[36] Methods for quantitation of camphor in biological samples include reverse phase high performance liquid chromatography (RP/HPLC) with UV detection and gas chromatography with flame ionization detection (GC/FID).[37] The limits of detection and quantitation of camphor in plasma following analysis by GC/FID are about 1 ng/mL and 5 ng/mL, respectively.[38] The between-day coefficient of variation for camphor in this study was about 13.5%.

Biomarkers

There are few data correlating clinical effects with concentrations of camphor in blood. Consequently, the presence of camphor in blood samples confirms exposure, but these biomarkers are not usually available in clinical laboratories. Two adults developed agitation and anxiety after ingesting camphor about 2 hours prior to presentation to the emergency department. Their initial plasma samples contained 0.3 mg camphor/L and 0.4 mg camphor/L.[15] Approximately 3 hours after ingesting camphorated oil, the plasma camphor concentration in blood samples from a 60-year-old woman was 3.1 mg/L.[39] Prior to blood sampling, she had two grand mal seizures, and at the time the blood sample was drawn, she had stable vital signs and was comatose (i.e., responsive only to painful stimuli). Following the intentional ingestion about 44 mL Campho-Phenique® (68 mg camphor/kg) 5 hours prior to sampling, the urine sample from a 20-year-old man contained 1.5 μg/mL camphor as measured by GC.[16] The serum concentration of camphor 7 hours after the ingestion of Vicks Vaporub® by a 3-year-old girl was 1.95 mg/dL. Although the patient developed confusion, vomiting, and suffered a single seizure within 2 hours of the camphor ingestion, the

patient had stable vital signs and regular respirations at the time the blood sample was drawn.[40] By 21 hours after ingestion, camphor was not detectable in the serum as measured by gas liquid chromatography.

Abnormalities

The chest x-ray is usually normal unless aspiration occurred during a seizure or altered consciousness. Most cases of camphor poisoning are not associated with laboratory changes with the exception of laboratory abnormalities related to seizures or respiratory depression during serious camphor intoxication.[41,42] Although some case reports associated changes in serum hepatic enzymes with the absorption of camphor, the role of camphor in these changes is unclear and any observed hepatic changes are usually transient.

TREATMENT

Stabilization

Because of the potential for rapid absorption of camphor and the quick onset of seizures, intravenous access should be established immediately in any patient with serious camphor intoxication (>30–50 mg/kg, the presence of alteration of consciousness, severe vomiting, ataxia, or seizures). Vital signs including pulse oximetry should be monitored closely. Sinus tachycardia is a common effect of camphor intoxication, but hypotension and shock are rare complications of camphor poisoning. Seizures should be treated with the usual doses of intravenous benzodiazepines. The use of intravenous phenobarbital is a second-line anticonvulsant based on older experimental studies and limited case reports.[3]

Decontamination

Referral to a health care facility is appropriate for camphor ingestions exceeding 30 mg/kg.[43] Because of the rapid absorption of camphor and the potentially rapid onset of seizures, the use of decontamination measures is not recommended. Although the low molecular weight of camphor suggests good adsorption to activated charcoal, there are limited data on the efficacy of activated charcoal. *In vivo* experiments in rats suggest that camphor is not well adsorbed to activated charcoal at a charcoal to camphor ratio of 2:1.[19] However, this study used a suboptimal dose of charcoal rather than the typical charcoal to toxin ratio of 10:1. Skin contaminated with camphor should be copiously washed with soap and water to prevent local irritant effects, although system toxicity is not expected to occur following dermal exposure to camphor.

Enhancement of Elimination

Camphor is highly lipophilic, and the large volume of distribution suggests that measures to enhance the elimination of camphor are not effective. Very small amounts of camphor appear in the urine unchanged, and diuresis does not significantly increase the renal elimination of camphor. Although a few case reports suggest that lipid hemodialysis[44] or resin hemoperfusion[45] improve the CNS effects (hyperexcitability, increased neuromuscular activity, seizures, coma) associated with serious camphor intoxication, the clinical data documenting the efficacy of these procedures are lacking. In a 54-year-old woman with coma, seizures, and respiratory failure after ingestion of 10% camphor spirits, 4 hours of hemoperfusion with Amberlite XAD4® (Sigma-Aldrich, St. Louis, MO) removed only 35 mg camphor.[21] Her seizures stopped during hemoperfusion, but she remained deeply comatose. Four hours of charcoal hemoperfusion in a comatose 60-year-old woman removed only about 1% of the estimated internal dose of camphor.

Supplemental Care

Although most laboratory values remain normal during camphor poisoning, patients with seizures or clinically significant CNS depression should be evaluated for any acid–base, electrolyte, glucose, or hepatorenal abnormalities. There are no specific antidotes for camphor poisoning. Patients with seizures during camphor intoxication should be monitored for at least 24 hours. Symptoms of camphor toxicity usually develop within 3 hours of ingestion; therefore, asymptomatic patients with a history of camphor ingestion may be discharged after 3–4 hours of observation.[3] In symptomatic patients, recurrence of toxic effects is not expected once the symptoms resolve. These patients may be discharged when symptoms of toxicity resolve.

Chapter 54

CASCARA
(*Frangula purshiana* Cooper)

HISTORY

The dried bark from *Frangula purshiana* Cooper (cascara sagrada) has a long history of use by Native Americans in the Pacific Northwest as a laxative. Reputedly, Spanish priests gave the name, Cascara sagrada, to the herbal preparation. The eclectic physician, J. H. Bundy, from Colusa, California contacted Parke, Davis & Company about the medicinal properties of the bark from Cascara sagrada. In 1877, this company introduced the bark as a cathartic in their publication, *New Preparations*. The *US Pharmacopeia* officially listed Cascara sagrada as an herbal remedy for constipation in 1890.

BOTANICAL DESCRIPTION

Common Name: Cascara sagrada

Scientific Name: *Frangula purshiana* Cooper (*Rhamnus purshiana* DC.)

Botanical Family: Rhamnaceae (buckthorn)

Physical Description: Cascara sagrada is an erect shrub with multiple stems that reach a height up to about 35–40 ft (~9–12 m). Young branches are slender and covered with reddish brown hairs; older branches are smooth and grayish. The small flowers have five greenish-white petals arranged in loose clusters. Individual plants contain both unisexual and bisexual flowers. The fruits are small, round black drupe with a yellowish inner pulp and tree glossy black seeds.

Distribution and Ecology: *Frangula purshiana* (cascara sagrada) is a native plant of the US Pacific Northwest.

EXPOSURE

Sources

The dried bark of this tree is a source for several anthraquinone laxatives including cascara. Other related plant species historically used as anthraquinone laxatives include *Frangula alnus* P. Mill. (*Rhamnus frangula* L.) and *Rhamnus cathartica* L. (common buckthorn). *Frangula alnus* is a shrubby tree native to Europe, western Asia, and North Africa that also occurs in the eastern United States as a non-native plant species. *Rhamnus cathartica* is indigenous to Europe and Asia, but this species also occurs in the northern United States as an introduced species. In contrast to the bark of *Frangula purshiana* and *Frangula alnus* (glossy buckthorn), the fruit of *Rhamnus cathartica* is the source of the herbal laxative. In addition to the dried bark of cascara sagrada, other preparations derived from bark include casanthranol (purified mixture of Anthranol glycosides), cascara sagrada extract (boiled extract of macerated bark powder), cascara sagrada fluid extract (boiled bark powder preserved in 20% ethanol), and aromatic cascara fluid extract (aqueous extract of dried cascara sagrada bark powder and magnesium oxide).

Medicinal Uses

Traditional

Popular stimulant herbal laxatives include senna (*Cassia senna* L., *C. angustifolia* Vahl.) and cascara. Dried exudate from aloe vera (*Aloe barbadensis*) also contains anthraquinone compounds, which induce diarrhea. Less

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

common herbal laxatives include Chinese rhubarb (*Rheum officinale* Baill.), frangula (*Frangula alnus*), and yellow dock (*Rumex crispus* L.).

Current

Oral laxatives include bulk-forming agents, stimulants, lubricants, and osmotic agents. Cascara contains anthracene glycosides, and this herbal laxative belongs to the stimulant class of laxatives along with senna. Diphenolic compounds (bisacodyl, phenolphthalein) are also stimulant laxatives. Osmotic laxatives include magnesium salts, sodium salts, and lactulose. Herbal laxatives (cascara, senna, frangula, aloe, rhubarb) are alternatives to other stimulant laxatives, such as synthetic diphenylmethane compounds (bisacodyl, phenolphthalein), docusate, dehydrocholic acid, and castor oil.

Regulatory Status

Cascara is an over-the-counter drug in the United States and Canada, and this substance is on the general sales list in the United Kingdom. Germany and France do not regulate the use of cascara.

PRINCIPAL INGREDIENTS

Chemical Composition

The basic structure for all anthranoid laxatives is an anthracene ring as demonstrated in Figure 54.1.[1] Anthranoid compounds refer to compounds with substitutions at C10 in the basic anthracene ring in Figure 54.1 as follows: anthrones, C10-H_2; anthraquinones, C10–O; dianthrones, C10—additional anthracene ring. Consequently, anthranoid compounds contain three aromatic rings joined in a linear arrangement that are termed anthraquinone compounds following the addition of two ketone groups.

Figure 54.2 demonstrates the general chemical structures of the three major groups (anthrones, anthraquinones, dianthrones) of anthranoid laxatives. The main

anthraquinone compounds in the bark extract from cascara sagrada are aloe-emodin, chrysophanol, and rhein, and the chemical structures of these anthraquinone compounds are displayed in Figure 54.3. Each of the major groups of anthranoid laxatives can be converted to another anthranoid compound by oxidative or reductive reactions as demonstrated in Figure 54.2. In plants, these anthranoid moieties (aglycon) are usually linked with a sugar (e.g., glucose, rhamnose) to a carbon at C10 (C-glycoside) or to a hydroxyl group at C1 or C8 (*O*-glycoside). The fresh bark of cascara sagrada contains free anthrones, anthrone-*O*-glycosides, anthrone-C-glycosides, aloe-emodin-*O*-glycoside, and dianthrones (i.e., two anthrones linked together).[2] During the drying process, the free anthrones and their corresponding *O*-glycosides are oxidized to dianthrone- and anthraquinone-*O*-glycosides to diminish the emetic properties of the bark extract. Bacterial β-glucosidase and reductase activity converts the inactive anthraquinone-*O*-glucosides into the pharmacologically active aglycon anthrones.

Dried bark from cascara sagrada contains about 8–10% hydroxyanthraquinone glycosides, which are hydroxyanthracene derivatives with hydroxyl groups at the C1 and C8 positions and sugar groups at the hydroxyl moiety (*O*-glycosides) or at the C10 position (C-glycosides).[3] Aloin compounds account for about 1–2% of the dried bark extract of cascara. A majority of the hydroxyanthracene compounds in dried bark extracts of cascara are cascarosides A–D (anthrone C-glycosides) as displayed in Figure 54.4. Cascarosides are primary glycosides of barbaloin. Cascaroside A is the C-10 isomer of 8-*O*-(β-D-glucopyranosyl)-(+) barbaloin, whereas cascaroside B is the corresponding diastereoisomer of 8-*O*-(β-D-glucopyranosyl)-(−) barbaloin.[4] Cascarosides C and D are diastereoisomers of primary C-glycosides of chrysaloin. Other ingredients of the dried bark extracts of cascara include barbaloin, chrysaloin aloe-emodin, deoxybarbaloin, chrysophanol, emodins, and oxanthrones as well as fatty acids (linoleic, myristic, syringic) and the volatile oil, rhamnol. Both barbaloin and chrysaloin are present in the dried bark extract of cascara as diastereoisomers. Figure 54.4 displays the chemical structure of the hydroxyanthracene compounds cascaroside A–D, barbaloin, and chrysaloin. During the extraction process, bianthraquinone glycosides are formed through the hydrolysis of bicascarosides in the extract.[5] These anthracene glycosides do not possess laxative activity.

Physiochemical Properties

Based on animal studies, cascarosides are more potent cathartics than the corresponding barbaloin.[6] Most primary glycosides in the bark extract of cascara are stable at pH 2; therefore, these compounds pass into the intestines with minimal degradation. Cascarosides have little taste in contrast to aloin compounds (e.g., barbaloin). The sugar moiety in anthraquinone glycosides confers hydrophilic properties to the molecule that limits absorption by intestinal epithelial cells.[7]

Mechanism of Toxicity

The exact mechanism of action by which anthranoid laxatives produce diarrhea is unclear. These compounds increase intestinal motility and intraluminal secretions by multiple mechanisms including stimulation of prostaglandin E2 formation,[8] platelet activating factor, and nitric oxide synthesis.[9] Rodent studies suggest the sen-

noside (dianthrone *O*-glycoside)-induced secretion of intestinal fluid is mediated, at least in part, by the release of serotonin.[10] Following oral administration of cascara, minimal absorption of anthranoid compounds occurs in the stomach and small intestine because of their large molecular size and hydrophilic properties. In the large intestine, bacteria metabolize these compounds to active aglycons, which directly affect intestinal absorption, secretion, and motility.[1] Chronic abuse of these compounds causes damage to the intestinal epithelium manifest by apoptotic bodies in the pigmented mucosa of the colon. These changes are characteristic of pseudomelanosis coli.

DOSE RESPONSE

Table 54.1 lists the standard dosage of cascara based on standard over-the-counter formulations defined by the *US Pharmacopeia*. Toxicity usually results from the chronic abuse of cascara, but the toxic dose is not well defined.

TOXICOKINETICS

Anthrone C-glycosides in cascara are prodrugs, which are not absorbed in the gastrointestinal tract until bacteria in the colon split off the sugar moiety.[11] Figure 54.5 displays the biotransformation of anthrone C-glycosides by bacteria in the gastrointestinal tract. In contrast to the dianthrone *O*-glycosides (e.g., sennosides A/B in senna), the anthrone C-glycosides in cascara are not easily metabolized by bacterial flora, and there is substantial variation in the response of different animal species to cascara.[6] For example, mice can break the *O*-glycoside link in cascarosides, but not the C-glycoside link. The released anthranoid aglycons (free anthrones) diffuse to the intestinal wall where they alter intestinal secretions and motility. The onset of action of the laxative effects is about 6–8 hours.[12] Animal studies suggest that some hydroxylation of these aglycons occurs after absorption in addition to the conjugation of the anthrone compounds to glucuronides and sulfates. At least some of these compounds are excreted in the bile and undergo enterohepatic recirculation, leading to prolonged action.

The maternal use of cascara is compatible with breastfeeding.[13] Stimulant laxatives may increase intestinal transit, theoretically reducing drug absorption. However, there are few data on the clinical significance of this potential drug interaction.

CLINICAL RESPONSE

Acute Effects

A single case report associated the use of cascara with the development of cholestatic hepatitis complicated by fibrosis, portal hypertension, and ascites.[14] Right upper quadrant pain, abdominal bloating, nausea, anorexia, and jaundice began 3 days after initiation of cascara (one 425 mg capsule of aged cascara sagrada bark with reported 5% cascaroside potency, 3 times daily). The case report did not include an analysis of the cascara capsules.

Chronic Effects

Chronic abuse of cascara is associated with melanosis coli, dehydration, and electrolyte imbalance (hypokalemia, mild systemic acidosis).[15] A case report associated the development of severe weakness and hypokalemia (serum potassium = 2.3 mEq/L) with the daily ingestion of 6 cascara tablets daily for many months.[16] Pseudomelanosis coli is a reliable marker of chronic laxative abuse (i.e., >9–12 months) that is specific for anthranoid drugs (aloe, cascara, frangula, and rheum); this marker occurs in about three-fourths of patients abusing anthraquinone laxatives.[17,18] The typical gross appearance of the mucosa of the colon is a reticular pattern of dark striations resembling alligator skin. The presence of dark brown-black granular pigment in macrophages residing in the lamina propria of the colon causes the characteristic histological appearance of pseudomelanosis coli.[19] Rarely, the abnormal pigmentation occurs in the gastric mucosa.[20] This pigment probably is lipofuscin rather than melanin; hence, the more appropriate name is pseudomelanosis coli rather than melanosis coli. No symptoms are typically associated with pseudomelanosis coli, except the adverse effects of chronic laxative abuse. The abnormal pigmentation associated

TABLE 54.1. Daily Dose of Cascara Based on Standard Preparations

Age	Daily Dose	Total Hydroxyanthracene Compounds	Daily Dose of Hydroxyanthracenes
Children (2–12 years)	150–500 mg	7–10%	10.5–50 mg
Adults	300–1000 mg	7–10%	21–100 mg

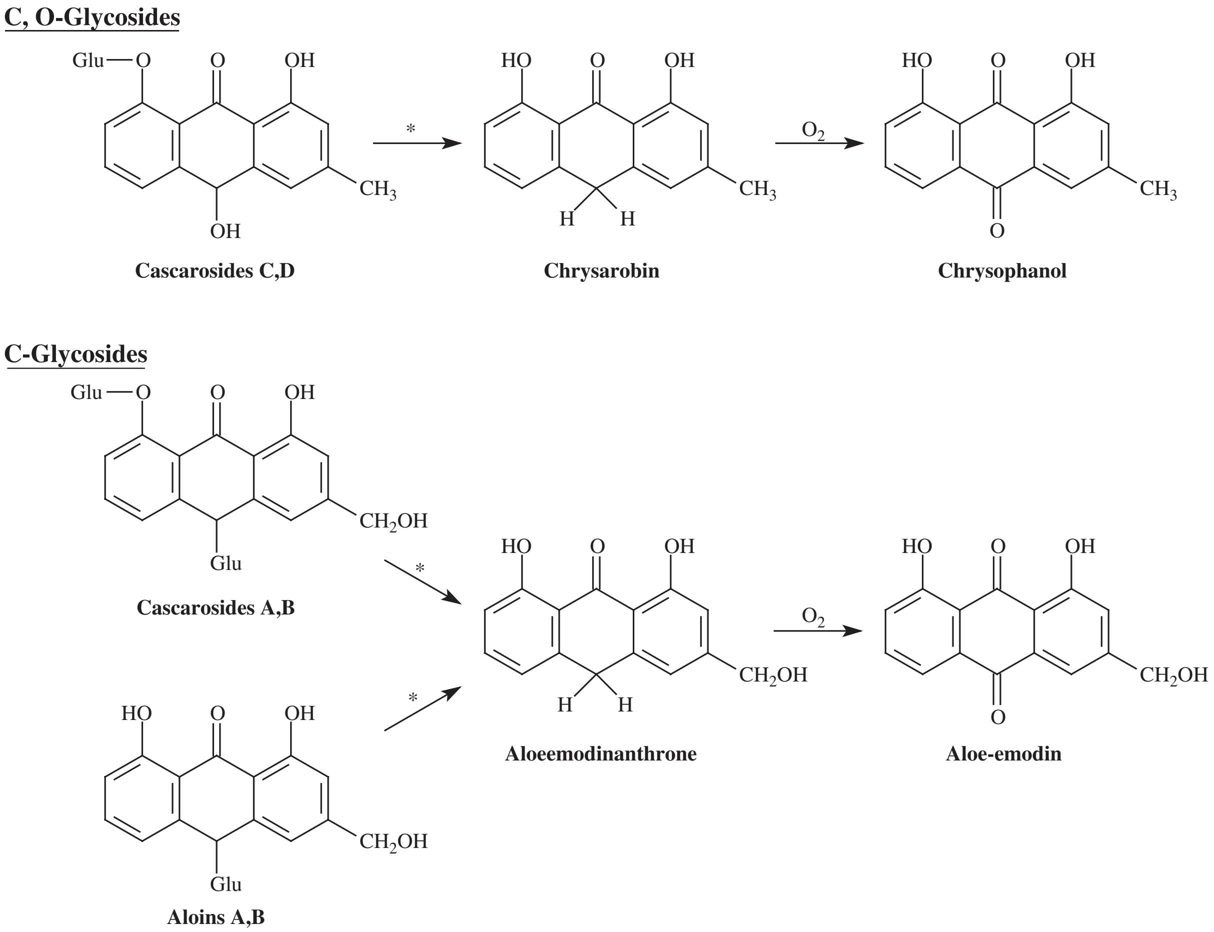

FIGURE 54.5. Biotransformation of cascara anthrone C-glycosides in the gastrointestinal tract. *Bacterial degradation.

with pseudomelanosis coli usually resolves within 6–11 months after cessation of anthranoid laxative use.[21]

Analysis of some,[22] but not all,[23] epidemiological studies suggests that the presence of pseudomelanosis coli (and laxative abuse) increases the risk of colorectal cancer severalfold (i.e., about 1.5–3). Although some retrospective case-control studies indicate an increased risk of colorectal cancer in patients with constipation and commercial laxative use, other prospective case-control studies have not confirmed the suspected increased cancer risk.[24] A meta-analysis of 14 case-control studies demonstrated statistically significant risks for colorectal cancer associated with both constipation and the use of cathartics.[25] The pooled odds ratios were 1.48 (95% CI: 1.32–1.66) and 1.46 (95% CI: 1.33–1.61), respectively. These low odds ratios in comparison to various dietary components (fat, meat, alcohol, low-vegetable or low-residue diets) suggests that this increased risk reflects confounding factors associated with dietary habits rather than true causation. There is inadequate evidence for the carcinogenicity of cascara or other anthraquinone laxatives (with the exception of 1-hydroxyanthraquinone) in animals.[26] A 13-week rodent study using cascara (140 mg/kg/d and 420 mg/kg/d) on azoxymethane-induced aberrant crypt foci and tumors did not detect promoting or initiating activity for the laxative (140 mg) and diarrheal (420 mg) dose of cascara.[27] Similarly, there is no clear evidence that the anthranoid compounds in senna extracts (sennosides, rhein, aloe-emodin) are genotoxic or carcinogenic.[28]

DIAGNOSTIC TESTING

Colorimetric analysis of hydroxyanthraquinone compounds (rhein, aloe-emodin, emodin) after hydrolysis and oxidation determines these compounds as a whole group rather than individual hydroxyanthraquinone compounds. High performance liquid chromatography can separate individual hydroxyanthraquinone compounds.[29] A rapid, simple method for the detection of

anthraquinone compounds in cascara along with other diphenolic laxatives (bisacodyl, phenolphthalein) is solid-phase extraction of urine samples coupled with high performance thin layer chromatography.[30] The detection limits are approximately 10–20 mg/L. Capillary gas chromatography/mass spectrometry allows the detection of anthraquinone metabolites in human urine samples along with other laxatives (e.g., bisacodyl, picosulfate, phenolphthalein).[31] The limit of detection in full scan mode ranges from 10–25 ng/mL with a coefficient of variation <15%.

TREATMENT

Treatment is supportive. Patients with chronic laxative abuse should be evaluated for evidence of fluid and electrolyte imbalance. Severe hypokalemia may develop following chronic abuse of cascara.

Chapter 55

CAT'S CLAW
[*Uncaria tomentosa* (Willd. ex Schult.) DC.]

HISTORY

Several Peruvian aborigine populations (e.g., Asháninka natives) have used extracts of cat's claw for centuries as a traditional treatment for infections and inflammatory reactions. The indigenous peoples in the Amazon rainforest and surrounding tropical areas (Colombia, Costa Rica, Ecuador, Guatemala, Guyana, Panama, Suriname, Venezuela) use two species of *Uncaria* [*U. tomentosa* (Willd. ex Schult.) DC., *U. guianensis* (Aubl.) J.F. Gmel.)] interchangeably for traditional medicinal applications.

BOTANICAL DESCRIPTION

The genus *Uncaria* contains at least 34 species widely distributed in tropical areas including Southeast Asia. The term cat's claw applies to two native Central and South American species, *Uncaria tomentosa* (yellowish-white flowers) and *Uncaria guianensis* (reddish-orange flowers). This genus is characterized by the appearance of short, hook-shaped peduncles on the side shoots that connect the flower calyxes to the main stems.

Common Name: Cat's Claw, Uña de Gato

Scientific Name: *Uncaria tomentosa* (Willd. ex Schult.) DC.

Botanical Family: Rubiaceae (madders family)

Physical Description: This tropical vine grows up to 100 ft (~30 m) in length with the main stem being up to 10 in. (~25 cm) in diameter. The fibrous bark is cinnamon in color with longitudinal striations. Young shoots have coarse hairs and curved hooks that resemble cat's claws. The yellowish-white flowers are tubular and the seed pods are long and sessile with oblong seeds.

Distribution and Ecology: *Uncaria tomentosa* inhabits areas at elevations of 1,000–2,500 ft (~300–800 m) in mature natural forests of Central (Panama, Costa Rica, Colombia, Guatemala, Honduras) and South (Peru, Ecuador, Venezuela) America, as well as Trinidad and Suriname.[2] *Uncaria guianensis* occurs at elevations of 300–1,500 ft (~100–450 m) in Peru, Venezuela, Bolivia, Paraguay, Guyana, Brazil, and Trinidad.

EXPOSURE

Medicinal Uses

TRADITIONAL

Decoctions of the bark of cat's claw are a traditional treatment for a variety of diseases including cancer, arthritis, gastritis, and infections.[1] Preparation of the decoction involves boiling the inner bark or the root bark, although traditional uses also include the addition of macerated bark to alcoholic beverages.[2] Asháninka priests in the Peruvian rainforest use extracts in rituals, and aqueous extracts of the bark are traditional treatments for a variety of illnesses including abscesses, allergies, arthritis, asthma, cancer, contraception, fever, gastric ulcers, menstrual irregularity, urinary tract inflammation, viral and bacterial infections, gastritis, and wounds.[3] Traditionally, indigenous groups produce an herbal decoction by boiling 20 g cat's claw root bark in

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

a liter of water for 45 minutes, and then replacing the evaporated liquid with water to produce one liter of decoction.[4]

Current

The main source of the active ingredients in herbal preparations of cat's claw is the root or stem bark. C-Med 100® (Human Genome Sciences, San Diego, CA) is a hot water extract of cat's claw (*U. tomentosa*) that contains compounds with molecular weights below 10 kDa and excludes higher molecular weight compounds (e.g., flavonoids, tannins). Commercial preparations of bark extracts from cat's claw [C-Med-100®, Activar AC-11® (Optigenex, Inc., New York, NY)] are based on oxindole alkaloid content rather than bioavailability or clinical efficacy. Small clinical trials suggest a potential role for extracts of cat's claw in the treatment of osteoarthritis[5] and rheumatoid arthritis.[6] Although these controlled clinical studies demonstrated some reduction in pain associated with cat's claw intake, there is insufficient objective evidence to confirm the clinical efficacy of this anti-inflammatory activity.[7]

Regulatory Status

In the United States, cat's claw is a dietary supplement as specified by the Definition of Certain Foods as Dietary Supplements, in Section 3 of the Dietary Supplement Health and Education Act, 1994. This substance has been classified as a dietary supplement since the late 1980s.

PRINCIPAL INGREDIENTS

Chemical Composition

Cat's claw contains at least 50 constituents including oxindole and indole alkaloids,[8] quinovic acid glycosides,[9,10] pyroquinovic acid glycosides (tomentosides A,B)[11], ursane-type pentacyclic triterpenes, procyanidins (cinchonain Ia and Ib), catechins, and sterols (β-sitosterol). The alkaloids of this plant have a spiro oxindole structure as demonstrated by Figure 55.1. The major alkaloids in crude extracts of bark and leaves of *Uncaria tomentosa* as determined by high performance liquid chromatography with photodiode array detection (HPLC/DAD) followed by HPLC coupled with electron spray ionization (HPLC/ESI) in positive ion mode include both pentacyclic (mitraphylline, isomitraphylline, pteropodine, isopteropodine, speciophylline, uncarine F) and tetracyclic alkaloids (ryncophylline, isoryncophylline).[12] Corynoxeine and isocorynoxeine are minor oxindole tetracyclic alkaloids, and uncarine C and E are the minor methyl esters of pteropodic and isopteropodic acids, respectively.[13] Oxindole alkaloids isomerize rapidly in aqueous solutions to form pH-dependent mixtures of isomers.[7] Variability in alkaloid content occurs with season, plant strains, and plant parts.[14] The major alkaloids in three samples of bark extract were pteropodine, isopteropodine, and isomitraphylline; mitraphylline and isomitraphylline were the major alkaloids in the leaves.[12] Total mean pentacyclic and tetracyclic alkaloid content in the bark extract were about 26.9 mg/g dry weight and 2.8 mg/g dry weight, respectively, compared with 14.2 mg/ g dry weight and 3.2 mg/g dry weight, respectively, in the leaves.

Physiochemical Properties

Several quinovic acid glycosides demonstrate anti-inflammatory activity in animal models. The bark is odorless with a slightly bitter, astringent flavor.[2] Animal studies suggest that components (e.g., quinic acid) in the hot water extract of the bark from *U. tomentosa* have some anti-inflammatory properties, such as inhibition of inflammatory cytokine tumor necrosis factor alpha and activation of the central transcription regulator, nuclear factor κB. The latter factor regulates the expression of proinflammatory cytokines and affects apoptosis. In a study of rodents, the administration of an industrial standardized *Uncaria tomentosa* fraction containing 95% oxindole alkaloids produced some systemic antinociceptive properties along with evidence of activation of 5-HT_2 receptors.[15]

Mechanism of Toxicity

Overall, animal studies using aqueous and hydroalcoholic extracts of cat's claw indicate a low degree of acute oral toxicity.[7]

DOSE RESPONSE

Establishing a dose-response curve for cat's claw is complicated by the variability in the concentration of active ingredients between different formulation, limited quantitative data, and inconsistent bioequivalence across different product formulas. The general range of the daily intake of cat's claw for inflammatory disorders is about 100–1000 mg, which corresponds to a daily consumption of 10–30 mg total alkaloids from *U. tomentosa*. The typical traditional daily dose for cat's claw decoction as described under Medicinal Uses is about 60 mL. Daily oral doses of C-Med-100® (8–10% or 16–20% carboxy alkyl esters) in clinical studies range from 250–700 mg.[16] There are inadequate data to determine the toxic dose of extracts from cat's claw.

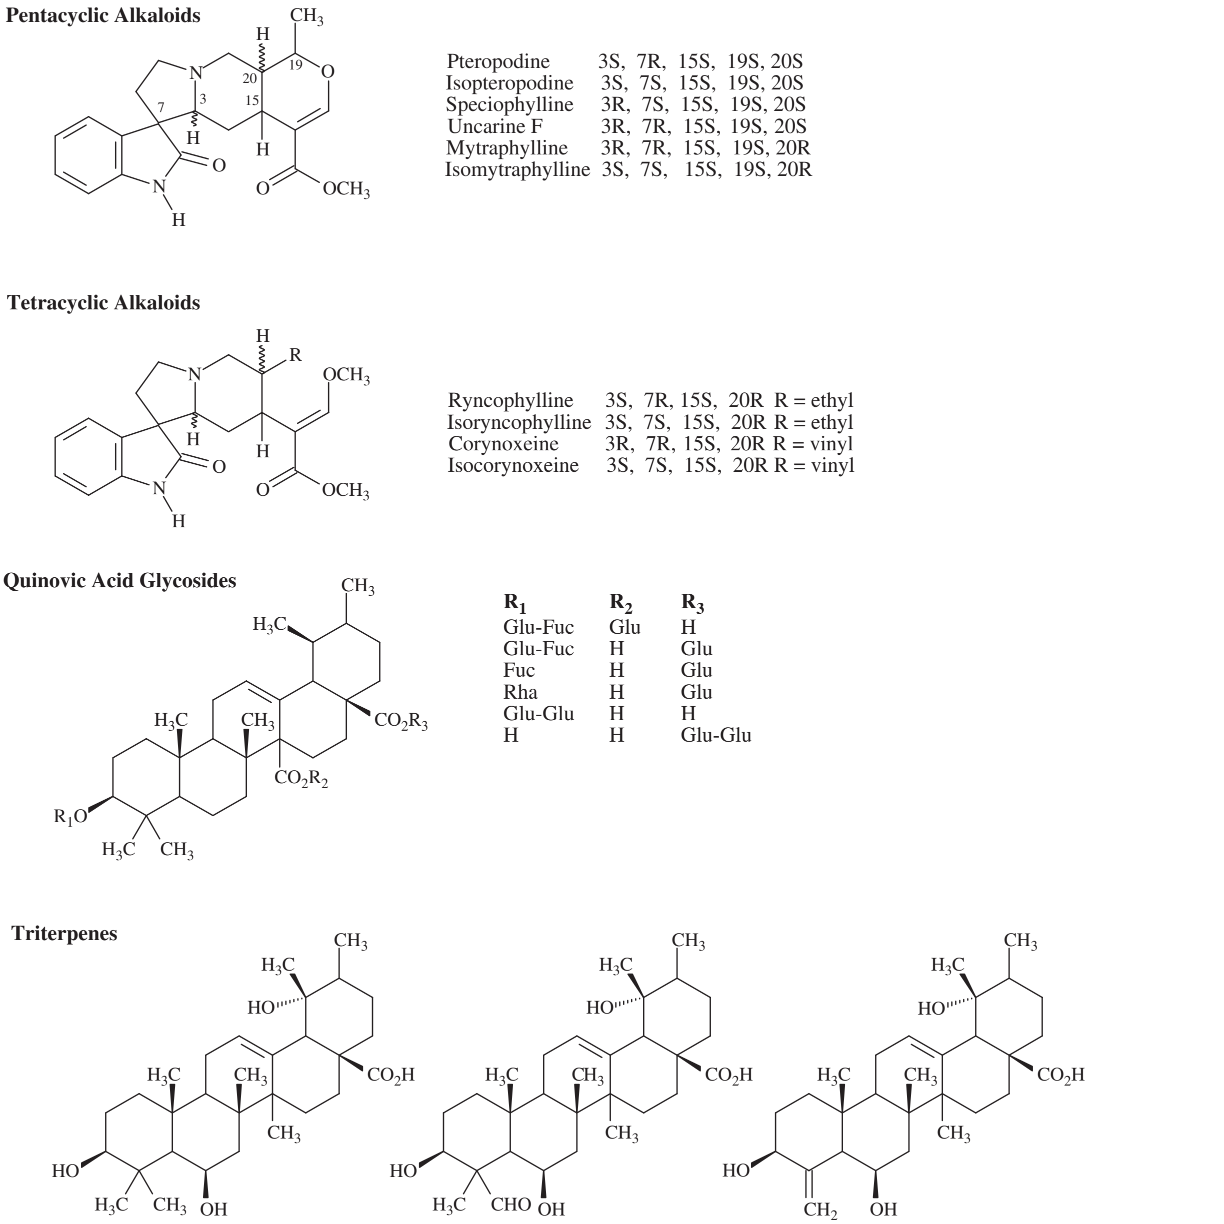

FIGURE 55.1. Chemical structures of pentacyclic and tetracyclic alkaloids, quinovic acid glycosides, and triterpenes in cat's claw. Adapted from Montoro P, et al. Identification and quantification of components in extracts of *Uncaria tomentosa* by HPLC-ES/MS. Phytochem Anal 2004;15;56. Copyright John Wiley & Sons Limited.

TOXICOKINETICS

There are few human data on the toxicokinetics of constituents in cat's claw. *In vitro* measurements of cytochrome P450 3A4 (CYP3A4) activity suggest some inhibitory activity through evaluation of extracts of cat's claw using a fluorometric microtiter plate assay.[17] However, there are inadequate clinical data to determine if metabolic inhibition of CYP3A4-dependent drugs (e.g., some benzodiazepines, cyclosporine, protease inhibitors, non-nucleoside reverse-transcriptase inhibitors) by cat's claw is clinically significant.

CLINICAL RESPONSE

In clinical trials, adverse effects associated with the administration of 20 mg of an aqueous acid-extracted dry extract of *Uncaria tomentosa* and 100 mg freeze-dried extract of *U. guianensis* were minimal, and there was no evidence of major side effects.[6] A case report

temporally associated the development of an allergic interstitial nephritis (increased renal insufficiency, proteinuria, hematuria) with the daily use of cat's claw in a 35-year-old woman with systemic lupus erythematosus.[18] The medications for her condition included prednisone, atenolol, metolazone, furosemide, and nifedipine. The proteinuria and hematuria resolved after cessation of cat's claw use, and the renal insufficiency improved.

DIAGNOSTIC TESTING

Methods to detect alkaloid and flavonol compounds in extracts of cat's claw include reverse-phase HPLC[19] and high performance liquid chromatography with electrospray mass spectrometry (HPLC/EMS).[12]

TREATMENT

Treatment is supportive.

Chapter 56

CHAMOMILE
[*Chamomilla recutita* (L.) Rauschert, *Chamaemelum nobile* L.]

HISTORY

The use of chamomile dates back at least to the ancient Greeks, who used this herb to treat fever. The word, chamomile, derives from the Greek word for the ground apple plant. The apple-like aroma of this plant was mentioned by Pliny the Elder in his book, *Naturalis Historia*, from the 1st century AD. Chamomile was part of monastery gardens during the Middle Ages, and European colonists brought chamomile to the United States in the 16th century.

BOTANICAL DESCRIPTION

Common Name: German Chamomile, Hungarian Chamomile, Wild Chamomile, Sweet False Chamomile, Mayweed

Scientific Name: *Chamomilla recutita* (L.) Rauschert (*Matricaria recutita*, *Matricaria chamomilla*)

Botanical Family: Asteraceae (Compositae, daisy)

Physical Description: German chamomile is an erect annual herb with branching stems that reaches 10–30 cm (~4–12 in.) in height. The leaves are alternate, tripinnately divided below and bipinnately divided leaves above. The small flower head (capitulum) grows up to 1.5 cm (0.6 in.) in diameter and is comprised of 12–20 white ligulate florets surrounding a conical hollow receptacle with numerous yellow tubular florets inserted. The fruit is small, yellow, and smooth.

Distribution and Ecology: German chamomile is a native herb of southeast Europe and west Asia that has spread throughout Europe, North America, and Australia.

Common Name: Roman Chamomile, English Chamomile, Common Chamomile

Scientific Name: *Chamaemelum nobile* L. (*Anthemis nobilis*)

Botanical Family: Asteraceae (Compositae, daisy)

Physical Description: This low-lying plant reaches up to about 1 ft (30 cm) in height. The gray-green leaves are thicker and closer to the ground than German chamomile. The flowers of Roman chamomile are similar to miniature daisies with yellow centers surrounded by white petals that smell like apples.

Distribution and Ecology: Roman chamomile is a perennial herb cultivated in western Europe and northern Africa.

EXPOSURE

Sources

Flos chamomillae consists of the dried flowering heads of *Chamomilla recutita* L. The yield of essential oil is typically at least 0.4% wet weight ranging up to about 1.5% wet weight. Powdered flos chamomillae is greenish yellow to yellowish brown.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Medicinal Uses

Traditional

The water and ethanol extracts of pulverized flower heads from German and Roman chamomile are popular, old remedies used for spasmolytic, wound-healing, antibacterial, anti-inflammatory, and sedative effects.[1,2] Traditional indications for chamomile tea include insomnia, indigestion, anxiety, fever, upper respiratory tract infections, headaches, skin and eye irritation, and burns. Chamomile is used both as an herbal tea and as an essential oil in cosmetics.

Current

Chamomile teas and extracts are traditional treatment for a variety of illnesses related to inflammation of the skin, upper respiratory tract, lungs, and gastrointestinal tract. The essential oil of chamomile is popular in aromatherapy. Previously, chamomile was evaluated as a mouthwash for the treatment of 5-fluorouracil-induced stomatitis with equivocal results.[3] There is an absence of clinical data evaluating the sedative properties of chamomile. An uncontrolled clinical series of 10 cardiac patients associated a "deep sleep" for 90 minutes with the administration of chamomile tea.[4]

Regulatory Status

Chamomile is regulated as a dietary supplement in the United States. The German Commission E approved the use of camomile for the treatment of skin and mouth irritation, bacterial skin diseases, and irritation of the respiratory tract, as well as the internal treatment of gastrointestinal spasm.

PRINCIPAL INGREDIENTS

Chemical Composition

The major constituents of essential oils from German and Roman chamomile are the esters, isobutyl angelate and 2-methylbutyl angelate. Other compounds present in teas extracted from the flower heads of chamomile are coumarin compounds, caffeic acid, flavonoids (apigetrin, apiin, apigenin, apigenin-7-*O*-glucoside, luteolin, luteolin-7-*O*-glucoside, matricin, quercetin, rutin), volatile oils (α-bisabolol, azulene, chamazulene), amino acids, choline polysaccharide, plant and fatty acids, tannin, and triterpene hydrocarbons (α-pinene, camphene, myrcene).[5,6] Apigenin is the most abundant flavonoid in chamomile flowers. Apigenin accumulates in the white florets of the camomile anthodium bound as apigenin 7-*O*-glucoside and various acylated derivatives.[7] In a study of Roman chamomile tea produced by pouring boiling water over the flowers and steeping for 15 minutes, the decanted tea contained only about 7% of the original oil content of the flowers.[8] Most of the water-insoluble chemicals (esters of angelic and butyric acid, α-pinene, myrcene, pinocarvone) were not detectable, whereas the water soluble compound, *t*-pinocarveol, was a much larger part of the tea than the essential oil.

The essential oil content of plant parts from chamomile depends on the chemotype and the season with typical essential oil content of flowers ranging from about 0.4–1.5%.[9] Commercial chamomile cultivars are classified according to bisabolol oxide (CAS RN:11087-43-7) content. α-Bisabolol [CAS RN:515-69-5] and bisabolol oxides are potentially active ingredients of chamomile tea. Figure 56.1 displays the chemical structure of bisabolol. The maximum essential oil content in the flower occurs immediately prior to flowering, and the oil content decreases after the flowering process.[10] The root of chamomile contains minor amounts (i.e., <0.1%) of essential oils (e.g., *trans*-β-farnesene). There are few clinical data on the potential active ingredients (e.g., apigenin, apigenin glycosides, α-bisabolol, bisabolol oxides, chamazulene, *trans*-β-farnesene) of chamomile tea.

Species in the Compositae family including chamomile contain allergenic sesquiterpene lactones (e.g., desacetyl matricarin, anthecotulide) as well as other constituents (e.g., polyacetylenes, thiophenes, coumarins) that may contribute to an acquired hypersensitivity.[11] As a result of the poor water solubility of some allergenic sesquiterpene lactones, hot-water extracts (i.e., teas) of chamomile contain fewer allergens than essential oil of chamomile used for medicinal purposes.[12] Matricin (CAS RN: 29041-35-8) is 6,7-guaianolide ($C_{17}H_{22}O_5$). Figure 56.2 displays the chemical structure of this sesquiterpene lactone. Chamazulene carboxylic acid is a decomposition product of matricin that forms during the steam distillation of the essential oil from chamomile.

Physiochemical Properties

The essential oil of chamomile has an intense blue color secondary to the presence of chamazulene (1–15%).

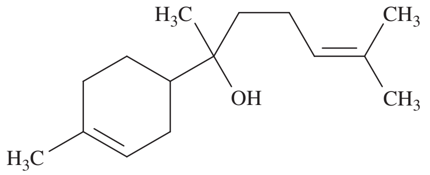

FIGURE 56.1. Chemical structure of bisabolol.

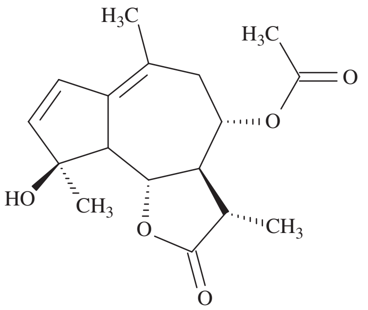

FIGURE 56.2. Chemical structure of matricin.

Mechanism of Toxicity

Radioreceptor binding assays for apigenin, a flavone constituent of chamomile, demonstrate some affinity for the central benzodiazepine binding site, but this affinity is relatively low. The $GABA_A$-benzodiazepine receptor antagonist, flumazenil, does not block this sedative action; consequently, the inhibitory activity of apigenin on locomotor behavior in rats probably does not result from an interaction with the $GABA_A$-benzodiazepine receptor.[13]

DOSE RESPONSE

The average adult dose is 2–8 g of the flower head (flos chamomillae) or 1–4 mL of the fluid extract (1:1 in 45% ethanol) 3 times daily.[9]

TOXICOKINETICS

There are few human data on the toxicokinetics of constituents in chamomile tea. *In vitro* data suggests that chamomile preparations contain constituents (e.g., chamazulene, *cis*-spiroether, *trans*-spiroether), which inhibit the activities of major human CYP450 isoenzymes, particularly CYP1A2.[14] Potential drug interactions resulting from the use of chamomile include increased anticoagulant effects due to coumarin content, inhibition of platelet aggregation, and the enhancement of sedative effects when used concomitantly with other central nervous system depressants. However, there are few data on the clinical significance of these potential drug interactions.[15] A case report associated the development of an elevated international normalized ratio (INR = 7.9) and internal hemorrhages with the use of chamomile tea by a 70-year-old woman, who was receiving coumarin for atrial fibrillation and a prosthetic heart valve.[16]

CLINICAL RESPONSE

Although the application of chamomile tea to the eye is a folk remedy for the treatment of conjunctivitis, allergic conjunctivitis can occur in sensitized patients following the application of these remedies.[17] Other hypersensitivity reactions to chamomile tea ranges from contact dermatitis, rhinitis, contact urticaria,[18] and facial edema[19] to acute anaphylaxis in individuals with allergies to ragweed or other members of the Compositae family, particularly following exposure to Roman chamomile (*Anthemis nobilis*).[20–22] A variety of allergens cross-react with chamomile including pollens from ragweed (*Ambrosia artemisiifolia* L.),[23] birch, and mugwort (*Artemisia vulgaris* L.).[25] In a series of 10 patients with documented allergies to chamomile, clinical effects resulting from the ingestion of chamomile tea included vomiting, diarrhea, abdominal cramps, rhinoconjunctivitis, dyspnea, and wheezing.[24] These patients also had variable cross-sensitivity to other allergens, such as celery roots, anise seeds, and pollen from mugwort, birch, and timothy grass. Life-threatening, immediate, IgE-mediated anaphylactic reactions can occur in hypersensitive patients. A case report associated the development of anaphylaxis (urticaria, laryngeal edema, hypotension, tachycardia) with the administration of an enema containing an oily extract of camomile flowers during labor.[25] An emergency cesarian section revealed an atonic, ischemic uterus, and the neonate died the following day. IgE-specific antibodies (RAST class = 2) were detected in blood samples from the mother.

DIAGNOSTIC TESTING

Methods for the analysis of the constituents of chamomile include high performance liquid chromatography (HPLC) with a diode-array detector or a fluorescence detector[26] and simultaneous isocratic HPLC.[27] Quantitation of apigenin in chamomile includes the use of gas chromatography/tandem mass spectrometry.[28] Additionally capillary electrophoresis can detect flavonoids, such as apigenin, with limits of detection and quantitation of approximately 4 μg/mL and 12 μg/mL, respectively.[29]

TREATMENT

Treatment is supportive and includes the use of standard treatment methods for contact dermatitis (topical steroids) or anaphylaxis (epinephrine, antihistamines).

Chapter 57

CHAPARRAL

[*Larrea tridentata* (Sesse & Moc. ex DC.) Vail]

HISTORY

The general term, chaparral, usually describes a type of thick, dense, drought-tolerant vegetation composed of shrubs and small trees. However, the herb chaparral is a preparation of *Larrea tridentata*. Aqueous extracts of chaparral are folk treatments primarily for renal and gynecological disorders by traditional healers in the southwestern United States and northern Mexico.[1] The Pima Indians in the Southwest used oral decoctions and aqueous extracts of the leaves and stems of chaparral for the treatment of diabetes.[2] In 1945, Waller and Gisvold first isolated the active ingredient (nordihydroguaiaretic acid) from chaparral.[3] Until 1967, nordihydroguaiaretic acid was added to a variety of products including frozen foods, oils, baking goods, and pharmaceutical preparations as an antioxidant that inhibited aerobic glycolysis. The use of nordihydroguaiaretic acid was discontinued in the 1960s when long-term rodent studies indicated that the chronic administration of nordihydroguaiaretic acid caused cystic nephropathy.[4] During the late 1960s, a case series of 59 patients with advanced cancer demonstrated that this compound was not an effective chemotherapeutic agent for these advanced tumors.[5] Animal studies during this period indicated that nordihydroguaiaretic acid produced renal toxicity; subsequently, this compound was removed from the list of substances "generally recognized as safe."

BOTANICAL DESCRIPTION

Chaparral is a shrub (i.e., contains woody stems) rather than an herb (nonwoody stems), but the leaves of chaparral are ground for use in traditional herbal medications (teas, capsules). The term chaparral frequently refers to species other than *Larrea tridentate*, including the South American varieties of creosote bush (*Larrea nitida* Cav., *Larrea cuneifolia* Cav.).

Common Name: Creosote Bush, Greaseweed, El Gobernadora, Hideonodo, Palo Ondo, Tasajo, Gumis

Scientific Name: *Larrea tridentata* (Sesse & Moc. ex DC.) [Synonyms: *Covillea glutinosa* (Engelm.) Rydb, *Larrea divaricata Cav., Larrea glutinosa* Engelm., *Larrea mexicana* Moric.]

Botanical Family: Zygophyllaceae (caltrop)

Physical Description: This plant is a well-branched, evergreen shrub that reaches heights up to 1–3 m (~3–10 ft). The stems are gray with swollen, black bands at the nodes, and the young branches are slender. The leaves are opposite, compound with two olive-green leaflets, which are glossy with resinous coating and an oblong to obovate shape. These leaflets are about 1 cm (~0.4 in.) in length and 3–5 mm (~0.1–0.2 in.) in width. The small, solitary flowers have five bright-yellow sepals (not petals), which are twisted like the blades of a fan. The fruit is a pea-sized globose capsule, which is covered by dense, white hairs. These fruits separate into five indehiscent, one-seeded carpels at maturity.

Distribution and Ecology: Chaparral inhabits the arid lands in northern Mexico and the southwestern United States from southeastern California to

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

southwestern Texas including New Mexico, Utah, Nevada, and Arizona. This ubiquitous shrub competes well with most other desert plants for environmental resources.

EXPOSURE

Sources

Chaparral is a Native American herb derived from the leaves and flowers of the desert shrub, *Larrea tridentata*. Ground leaves, stems, and/or flowers are usually ingested either as a brewed tea or a capsule. Although used primarily as a tea, other available forms of chaparral preparations include alcoholic extracts of the leaves and twigs, capsules, tablets, and poultices or fomentations of leaves and branches. The volatile oil represents about 0.1% of dried leaves and stems.

Medicinal Uses

Traditional

Traditional uses of this herb involve the purported anti-inflammatory, antimicrobial, antioxidant, and antineoplastic properties. Traditional healers in the southwestern United States and northern Mexico primarily used chaparral for the treatment of kidney stones, diabetes, and infertility.[1] Other herbal uses included the treatment of arthritis, rheumatism, inflammation, venereal diseases, abdominal pain, and infectious agents (e.g., varicella, skin infections).

Current

The use of chaparral as an herbal remedy is not recommended because of the lack of documented efficacy and the risk of hepatorenal damage. Clinical data does not support the use of this herb in the treatment of cancer, and animal studies suggest that chronic administration of the principal ingredient of chaparral, nordihydroguaiaretic acid (NDGA), may cause renal damage.[5] The chronic administration of feed containing 2% NDGA to rats produced renal cysts, vacuolation of the renal tubular epithelium, partial obstruction of nephrons, and hyperplasia of the collecting ducts.[6,7] Other herbal uses included the treatment of dandruff, bronchitis, arthritis, upper respiratory tract infections, tuberculosis, toothaches, venereal disease, rheumatism, menstrual cramps, and muscle spasms. Additionally, chaparral is ingested as a nutritional supplement.

Regulatory Status

Prior to 1967, nordihydroguaiaretic acid was a food additive that was used to prevent fermentation as a result of its antioxidant properties. The US Food & Drug Administration (FDA) removed chaparral from the list of substances "Generally Recognized as Safe" (GRAS) in 1968 when animal studies indicated that the chronic administration of NDGA in feed caused renal cysts and obstruction of nephrons. As a result of case reports associating serious hepatic damage with the use of chaparral teas, the FDA recommended the withdrawal of chaparral products in 1992.

PRINCIPAL INGREDIENTS

Chemical Composition

Nordihydroguaiaretic acid (NDGA, CAS RN: 500-38-9) is the principal ingredient in chaparral. Figure 57.1 displays the chemical structure of NDGA ($C_{18}H_{22}O_4$). Although the leaves, green stems, small woody stems (<5 mm/~0.2 in.), and flowers all contain NDGA, the highest concentrations of NDGA are found in the leaves and green stems. In a study of NDGA in chaparral, the leaves and green stems contained NDGA concentrations of 38.3 mg/g and 32.5 mg/g, respectively.[8] This plant contains a variety of compounds including volatile oils (calamine, eudesmol, limonene), lignans (nordihydroguaiaretic acid, norisoguaiacin, dihydroguaiaretic acid), flavonoids (isorhamnetin, kaempferol, quercetin, gossypetin, herbacetin), and amino acids (arginine, cystine, glutamic acid, glycine, isoleucine, leucine, phenylalanine, tryptophan, tyrosine, valine).

Physiochemical Properties

NDGA is a white crystalline solid with antioxidant properties. This compound also inhibits the lipoxygenase and cyclo-oxygenase pathways. Methyl and vinyl ketones contribute significantly to the characteristic, creosote-like odor of chaparral.[1]

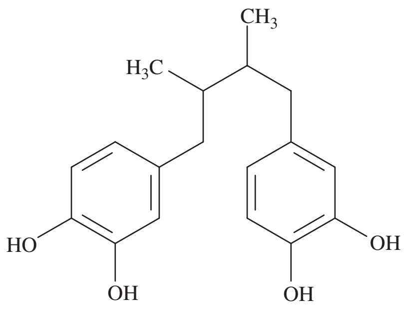

FIGURE 57.1. Chemical structure of nordihydroguaiaretic acid.

Mechanism of Toxicity

The mechanism of hepatotoxicity following chaparral use is probably idiosyncratic as the hepatotoxicity of NDGA has not been reproduced in animal models. Most biopsies from patients with suspected chaparral-induced liver damage are suggestive of cholestatic hepatitis.[9] Liver biopsies of patients with hepatitis after the use of chaparral demonstrate cholestatic injury manifest by acute inflammatory infiltrates, focal acute pericholangitis, mild ductal dilation, and proliferation of bile ductules in periportal areas as well as necrosis of hepatocytes. In severe cases, liver biopsies reveal severe acute hepatic necrosis with areas of lobular collapse, nodular regeneration, marked bile duct proliferation, mixed portal inflammation, and occasional fibrosis.[10]

DOSE RESPONSE

Medicinal Use

Although the FDA does not recommend the use of chaparral, some naturopathic practitioners use small doses of chaparral in complex herbal preparations.[11] In the United States between 1945 and 1967, nordihydroguaiaretic acid was an antioxidant added to food in concentrations of 0.01–0.02%. In preliminary, uncontrolled cancer chemotherapy studies, the administration of 250–3,000 g NDGA daily as a tea to humans did not produce any hematological or chemical abnormalities.[5]

Toxicity

The development of hepatitis following the use of chaparral tea is probably an idiosyncratic reaction; therefore, there is no clear dose response between the amount of chaparral tea and the severity of the hepatitis. Observational studies in humans did not detect hepatic damage in patients receiving daily doses of NDGA up to 400 mg /kg for the treatment of cancer.[5] In contrast, the development of cholestatic hepatitis was temporally associated with daily ingestion of 160 mg chaparral tablets for about 2 months.[12] Most case reports associating the use of chaparral with the development of hepatitis involve the use of chaparral within about 2–3 months of presentation to a health care facility for symptoms of hepatitis.[13]

TOXICOKINETICS

The major metabolite of NDGA is σ-quinone, which produces acute renal tubular dysfunction in rodents due to the accumulation of desquamated epithelial cells in the proximal tubules.[6,14] These studies indicate that the kidneys excrete little free NDGA in the urine, and the major detoxification pathway for this lignan is glucuronidation.[15] Excessive doses of chaparral may interfere with monoamine oxidase inhibitors as result of the presence of amino acid constituents, but there are few clinical data to confirm the clinical importance of this potential drug interaction.

CLINICAL RESPONSE

Adverse Reactions

Case reports associate dermal exposure to chaparral with the development of rash and stomatitis. Although the skin lesions occurred predominately in sun-exposed areas, the presence of lesions in other parts of the body and positive patch tests suggest an allergic contact dermatitis rather than a photodermatitis or irritant reaction.[16]

Toxic Effects

Sporadic case reports associate the ingestion of chaparral tea[17] and chaparral leaf[18] with the development of serious liver toxicity ranging from asymptomatic elevation of serum hepatic aminotransferases to fulminant hepatic failure.[19] Clinical manifestations of these hepatic effects include malaise, anorexia, nausea, retrosternal burning pain, pruritus, dark urine, jaundice, pedal edema, and distention of the abdomen. Resolution of these symptoms occurs over several months, and some focal scarring of the liver can persist.[18,20] In a case series of 18 patients with suspected chaparral-induced hepatitis, the range of chaparral use was 3–52 weeks, and resolution of symptoms ranged from 1–17 weeks after cessation of chaparral use in those patients without severe liver disease.[19] Four of these patients developed cirrhosis, and 2 patients required orthotopic liver transplantation due to fulminant hepatic failure. Renal damage is not usually associated with the ingestion of chaparral, but renal failure can occur as a complication of sepsis, hypotension, or the administration of nephrotoxic antibiotics associated with hepatic failure. Other herbal medicines associated with hepatitis include Chinese herbs (Jin Bu Huan, Ma-Huan, Sho-saiko-to), pyrrolizidine alkaloid-containing plants (*Crotalaria*, *Heliotropium*, *Senecio*, *Symphytum* spp.), skullcap (*Scutellaria laterifolia*), atractyloside-containing plants (*Atractylis gummifera* L., *Callilepis laureola* DC.), and germander (*Teucrium chamaedrys* L., *Teucrium polium* L.). Drugs associated with cholestasis and hepatitis include amoxicillin-clavulanate, azathioprine, carbamazepine, chlorpromazine, macrolide antibiotics, nonsteroidal anti-inflammatory drugs, oxypenicillins, and tricyclic antidepressants.[21] A case report associated the chronic

consumption of chaparral tea with the development of cystic renal disease and cystic adenocarcinoma of the kidney.[22] However, there are insufficient human data to determine a causal relationship between chaparral use and cancer.

DIAGNOSTIC TESTING

Analytical Methods

High performance liquid chromatography with UV detection and mass spectrometry can determine the phenolic constituents (e.g., lignans, flavonoids) found in chaparral.[23]

Biomarkers

There are no specific biomarkers of chaparral-induced hepatitis because the specific hepatotoxin has not been identified.

Abnormalities

Laboratory abnormalities associated with hepatitis include elevation of serum hepatic aminotransferases, hypoprothrombinemia, hyperbilirubinemia, and elevated serum alkaline phosphatase. Elevations in serum alkaline phosphatase concentrations are typically minimal to mild compared with the substantial increases in the serum alanine aminotransferase concentration. Fulminant hepatic failure can develop along with hepatic encephalopathy (obtundation, elevated serum ammonia concentration).

TREATMENT

Treatment is supportive and includes withdrawal of chaparral in cases of allergic or idiosyncratic reactions.

Chapter 58

CHASTE TREE
(*Vitex agnus-castus* L.)

HISTORY

Chaste tree is a native shrub of Mediterranean Europe that has been used since ancient Greek and Roman times as an herbal treatment for female reproductive problems. In the 4th century BC, Hippocrates recommended this herb for splenic injuries and inflammation.[1] The name of this herb derives from the Latin words for chastity (*castitas*) and lamb (*agnus*), and the name chaste tree refers to the belief that the use of this herb reduces sexual desire in women and encourages celibacy in members of religious orders. Pliny the Elder (AD 23–79) documented the use of this herb by Athenian women to preserve their chastity at the Thesmophoria by covering their beds with the foul-smelling leaves.[2] He also mentioned the use of this herb for the treatment of fever, flatulence, diarrhea, dropsy, and splenic diseases. In the *De Materia Medica* from about 55 AD, Dioscorides recommended a decoction of the seeds of the chaste tree for initiating lactation and menstruation. European herbalists used this herb to stimulate the uterus and promote menstruation, but the popularity of the herb waned until the middle 1900s.

BOTANICAL DESCRIPTION

Common Name: Chaste Tree, Chasteberry, Monk's Pepper

Scientific Name: *Vitex agnus-castus* L.

Botanical Family: Verbenaceae (verbena family)

Physical Description: This deciduous, aromatic plant ranges in size from a shrub to a small tree 3–9 ft (~1–3 m) tall. The leaves are opposite and palmately compounded with 5–7 leaflets and the underside is white-felted. Long spires of pale lilac or rose-colored flowers produce gray-brown fruits (drupes) with hard coverings. The dry fruits are the size of a black peppercorn, and these drupes contain four seeds.

Distribution and Ecology: This plant is indigenous to Mediterranean Europe and Central Asia.

EXPOSURE

Sources

Chaste tree extract is available as an herbal preparation, usually as a liquid (e.g., ethanol extract) or dried powder. The concentration of casticin in eight commercial samples of agni-casti fructus ranged from 0.025–0.212%, as measured by high performance liquid chromatography (HPLC).[3]

Medicinal Uses

TRADITIONAL

The fruit extract of chaste tree is a common folk medicine for female-related problems, including premenstrual syndrome, menstrual irregularity, infertility, acne, menopause, inadequate lactation, and hyperprolac-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

tinemia. Other uses of this herb include the treatment of fluid retention, indigestion, fungal infections, and anxiety. The chaste tree is not used in traditional Chinese or Indian (Ayurvedic) medicine.[2]

Current

This herb is typically administered as either an extract or as the dried ripe fruit of the chaste tree. The extract is usually standardized to contain a specified concentration of agnuside, aucubin, or casticin. Many commercial preparations contain 0.5% agnuside. Some studies support the use of chaste tree preparations for the treatment of menstrual disorders, but there is a lack of well-designed studies to document the efficacy of this herb for the treatment of female-related problems. In a prospective, open-label study of a 20 mg extract of the fruits of *Vitex agnus-castus* L., 20 of 43 women reported a reduction in premenstrual symptoms based on self-assessment using the Moos' menstrual distress questionnaire and a visual analogue scale.[4] The main response was related to the intensity rather than duration of symptoms. The extract was standardized to casticin. In a prospective, randomized, placebo-controlled study of 170 women with premenstrual syndrome, 52% of the treatment group responded to the treatment compared with 24% of the placebo group.[5] The treatment group received 20 mg daily of an ethanol extract of *Vitex agnus-castus* (Ze 440, Zeller AG, CH-Romanshorn). A responder was defined by a 50% reduction in premenstrual symptoms over three menstrual cycles based on self-assessment. A preliminary, single-blind, rater-blinded, prospective study compared the use of fluoxetine and *Vitex agnus-castus* extract to treat premenstrual dysphoric syndrome. The study did not demonstrate a statistically significant difference in response between the two treatment groups.[6] There was no placebo group. A double-blind, placebo-controlled study of the efficacy of a *Vitex agnus-castus* extract (Mastodynon®, Bionorica Arzneimittel GmbH, Neumarkt, Germany) for cyclical mastalgia detected an initial reduction in pain scores during the first menstrual cycle, but after three cycles the difference between treatment and placebo groups was not statistically significant (p = 0.064).[7] There are no clinical data to support the use of this herb to enhance breast size.[8]

Regulatory Status

The German Commission E approves the use of chaste tree extract for premenstrual tension, menstrual irregularities, and breast pain. Chaste tree extract is a dietary supplement in the United States and the United Kingdom.

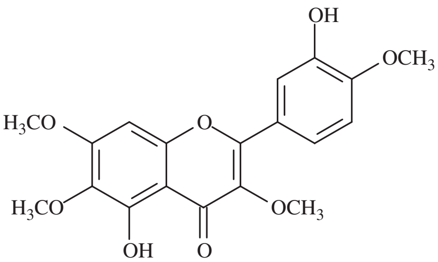

FIGURE 58.1. Chemical structure of casticin.

PRINCIPAL INGREDIENTS

Chemical Composition

Extracts of chaste tree contain a variety of constituents including flavonoids (casticin, isovitexin, orientin), iridoid compounds (aucubin, agnuside, agnucastoside A, B, and C, mussaenosidic acid), monoterpene, diterpene (vitetrifolin B and C), and sesquiterpene compounds, castine (bitter principle), and linoleic acid.[9,10] Figure 58.1 displays the chemical structure of the flavonoid, casticin (CAS RN:479-91-4). The leaves, flowers, and fruits of chaste tree contain essential oils that vary in composition depending on distillation technique as well as geographical and environmental factors. The main constituents of a hydrodistillate of mature fruit from chaste tree were sabinene (16–44.1%), 1,8-cineole (8.4–15.2%), β-caryophyllene (2.1–5.0%), and *trans*-β-farnesene (5.0–11.7%).[11]

Mechanism of Toxicity

The active ingredient in chaste tree extracts has not been identified. *In vivo* human studies suggest that chaste tree preparations contain dopamine agonists that bind to D_2 receptors and inhibit the release of prolactin.[12] Extracts of *Vitex agnus-castus* contain diterpene compounds (clerodadienols) with potential dopaminergic activity.[13] *In vitro* studies also suggest that constituents in *Vitex agnus-castus* extract bind to mu and kappa opioid receptors.[14] Methanol extracts of the fruit from this herb probably do not have clinically significant estrogen agonist activity based on recombinant cell bioassay.[15] However, these extracts contain linoleic acid, which can bind to estrogen receptors (ERα, ERβ).[16]

DOSE RESPONSE

Recommended daily doses for relief of the symptoms of premenstrual tension include 175–225 mg/d of chaste tree or *Vitex agnus-castus* extract standardized to contain 0.5% agnuside and water/ethanol chaste tree extracts

equivalent to 20–40 mg of fresh berries. The toxic dose of chaste tree extract is not well defined.

TOXICOKINETICS

The active ingredients in chaste tree extract are not well defined; therefore, there are few data on the toxicokinetics of these compounds. Although theoretically chaste tree extract can interact with dopamine antagonists, there are few data to indicate that the use of this herb causes clinically significant drug interactions.

CLINICAL RESPONSE

There are few data on the toxicity of chaste tree extracts. Adverse events following treatment with chaste tree extract are usually mild and reversible. The most common adverse reactions reported during the use of this herb are headache, nausea, abdominal pain, indigestion, acne, and allergic reactions (erythematous rash).[1]

DIAGNOSTIC TESTING

HPLC methods are available to determine the concentration of casticin in chaste tree extract.[3]

TREATMENT

Treatment is supportive with few toxic effects expected following exposure to chaste tree extracts.

Chapter 59

CLOVE and EUGENOL
[*Syzygium aromaticum* (L.) Merr. & L. M. Perry]

HISTORY

Clove has been used as a spice and fragrance in China for over 2000 years. References to the medicinal use of clove oil for the treatment of toothache in Europe date back at least to the 17th century, when the use of clove oil was recommended in the *Practice of Physic*, published in France in the 1640s.[1] Clove oil and the main active ingredient, eugenol, have been popular ingredients of consumer products (i.e., soaps, detergents) since the 19th century in the United States. During the late 19th and early 20th centuries, clove oil was a popular source of eugenol for use in the synthesis of vanilla. Eugenol was isolated from clove oil in 1929, and commercial production of eugenol began in the United States during the early 1940s.[2] Clove cigarettes (kreteks) are an alternative form of tobacco use along with cigars and bidis (small hand-rolled cigarettes from India) that are particularly fashionable with youth. These cigarettes were popular in Australia during the 1970s and in the United States during the 1980s. In 1984 and 1985, the US Centers for Disease Control received 11 case reports associating the development of acute respiratory symptoms with the use of clove cigarettes.[3] These reports included two deaths, but the details of these cases were not well defined. Extensive publicity associated with these case reports and concerns about the health effects of kreteks resulted in a sharp decrease in the consumption of these cigarettes in the United States beginning in the late 1980s. As with tobacco cigarettes, the use of clove cigarettes (kreteks) among middle school and high school students currently is declining in the United States. In 2002, the current use (i.e., within the last 30 days) of clove cigarettes among middle school and high school students was 2.0% and 2.7%, respectively, as measured by National Youth Tobacco Survey.[4]

BOTANICAL DESCRIPTION

Common Name: Clove

Scientific Name: *Syzygium aromaticum* (L.) Merr. & L. M. Perry (*Eugenia caryophyllata*)

Botanical Family: Myrtaceae (myrtles)

Physical Description: The clove tree is a small, tropical evergreen that grows up to 20 ft (~6 m) tall. The large leaves are oblong up to 10 in. (~25 cm) long and 4 in. (~10 cm) wide.

Distribution and Ecology: The clove tree is indigenous to the Philippines and nearby islands, but this tree is widely cultivated in many tropical countries. Zanzibar and Mozambique are major producers of cloves and clove oil.

EXPOSURE

Sources

Commercial clove oil is a steam distillation product obtained from clove leaves or buds, which contain up to 84–88% eugenol. Eugenol is widely distributed in the plant kingdom, particular in cinnamon leaf and bark oil, basil oils (*Ocimum gratissimum* L.), and sweet basil essential oil (*Ocimum basilicum* L.). Further distillation

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

of clove oil produces a refined product containing almost pure eugenol (i.e., >95%). Various whiskies aged in oak barrels contain eugenol (i.e., up to about 0.5 mg/L) as a result of the diffusion of the phenolic fraction of an ethanol extract of oak.[2] Clove cigarettes ("kreteks") are tobacco products exported from India that contain about 60% tobacco and 40% shredded clove buds. In Indonesia, clove cigarettes are smoked in a conventional manner. However, in the United States younger smokers typically inhale the smoke from kreteks deeply and then perform a Valsalva maneuver to maximize the delivery of the smoke to the alveoli in a manner similar to "toking" a marijuana cigarette.[5]

Uses

Traditional

Traditional uses for clove oil in Chinese medicine include use as an antimicrobial agent,[6] antispasmodic, antiparasitic agent, and a carminative for the treatment of excessive intestinal gas. Clove oil has insect-repellant properties. In a study of 38 essential oils, clove oil was the most effective mosquito repellant providing 100% repellency for 2–4 hours against three species of mosquitos. Clove oil was not directly compared with DEET (*N*,*N*-diethyl-meta-toluamide).[7]

Current

Clove oil is marketed over-the-counter in the United States as a topical dental analgesic and antiseptic, a flavoring agent in food, mouthwashes, and pharmaceutical products, and as an ingredient in aromatherapy. Eugenol is also a fragrance and flavoring agent, a zinc oxide-based dental analgesic, an insect attractant (Japanese beetles), and a chemical intermediate.

Regulatory Status

In the United States, eugenol and clove oil are generally recognized as safe food additives (GRAS), and the US Food and Drug Administration (FDA) has approved the use of eugenol and clove oil in foods.[8] Eugenol is also approved for use in the manufacture of textiles and textile fibers that contact food surfaces. Additionally, eugenol and clove oil are approved for use as over-the-counter dental analgesics.

PRINCIPAL INGREDIENTS

Chemical Composition

Clove oil represents slightly less than 25% of the weight of ground cloves as measured by ion trap gas chromatography/mass spectrometry.[9] Commercial clove oil contains eugenol in amounts ranging from approximately 50–88%, depending on the source. Other components of clove oil include eugenol acetate and β-caryophyllene. The content of eugenol in clove oil depends on the distillation process, geographic location, soil characteristics, and climate. Dried clove buds contain about 15% weight/volume clove oil (i.e., 120–130 mg/g dry clove buds). A commercial sample of clove oil contained about 70% eugenol and 15% β-caryophyllene, whereas a sample of clove bud extract from an Italian herb shop contained approximately 15% eugenol and 4% β-caryophyllene as measured by micellar electrokinetic capillary electrophoresis with diode array detection.[10]

Indonesian clove cigarettes contain approximately 60% tobacco and 40% shredded clove buds. In addition to the components from tobacco smoke, the smoke from clove cigarettes contains eugenol, β-caryophyllene, and minor amounts of eugenol acetate, α-humulene, and caryophyllene-epoxide.[24] The smoke from these cigarettes does not contain unique pyrolysis products when compared with tobacco smoke. Analysis of a popular clove cigarette (Djarum Special) indicated that the nicotine content of the rod filler of the cigarette was lower (7.4 mg) than conventional American cigarettes (13 mg).[11] However, the average smoking time and number of puffs are usually greater during clove cigarette smoking than conventional cigarette smoking. In a study of 10 smokers, the venous plasma nicotine concentrations and exhaled carbon monoxide concentrations were similar during clove cigarette and conventional cigarette smoking.[11]

Physiochemical Properties

Eugenol is a weakly acidic phenolic compound (CAS RN: 97-53-0, 4-allyl-2-methoxy-phenol), which is volatile and slightly water soluble. Figure 59.1 displays the structure of eugenol. This compound is colorless to pale-yellow liquid with an odor of cloves and a spicy, pungent taste. *In vitro* studies indicate that eugenol and acetyl eugenol inhibit cyclooxygenase and platelet aggrega-

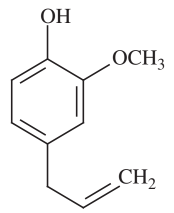

FIGURE 59.1. Chemical structure of eugenol ($C_{10}H_{12}O_2$, MW 164.2).

TABLE 59.1. Physical Properties of Eugenol

Physical Property	Value
Conversion Factor	1 ppm = 6.71 mg/m^3
Melting Point	–7.50 °C/18.5 °F
Boiling Point	253.2 °C/487.76 °F
Vapor Pressure	10 mmHg (123 °C/253 °F)
pK_a Dissociation Constant	10.19 (25 °C/77 °F)
log P (Octanol-Water)	2.27
Water Solubility	2,460 mg/L (25 °C/77 °F)
Henry's Law Constant	4.81E-08 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	6.50E-11 cm^3/molecule-second (25 °C/77 °F)

tion, reduce thromboxane synthesis in platelets,[12] and enhance lipoxygenase metabolism.[13,14] The smoke from clove cigarettes is sweetly aromatic with some numbing of the mouth occurring after inhalation of the smoke. Table 59.1 lists some of the physical properties of eugenol.

Mechanism of Toxicity

Lungs

Animal studies to date have not demonstrated unique or highly toxic constituents in the smoke from clove cigarettes. A short-term study of rats exposed to smoke from tobacco and clove cigarettes for 30 minutes did not detect significant differences in body weights, food and water intake, respirations, or histological abnormalities between the tobacco-only group and the clove + tobacco group with the exception of higher carbon monoxide concentrations in the tobacco-only group.[15] A similar 14-day study of rats exposed to 15 minutes of smoke up to 6 times daily did not detect any unique histological or clinical effects in the kretek group.[16] There was a statistically significant increase in lung weights in the tobacco-only group, when compared with the kretek group. These studies were criticized because of the lack of statistical power, small group size (5 rats per group), and inability of the study to replicate actual human exposure to kretek smoke including the potential for aspiration.[17] The intratracheal instillation of 10% eugenol in doses up to 24 mg eugenol/kg produced interstitial hemorrhage, acute emphysema, and acute pulmonary edema in the lungs of the exposed rats.[18] However, exposure of male Syrian golden hamsters to kretek smoke from up to 30 cigarettes daily was not associated with any histological abnormalities in the lungs, trachea, larynx, nasal cavity, esophagus, kidney, or bladder. The estimated daily dose of eugenol was up to 2 mg/kg body weight.

Liver

In vitro studies indicate that cytochrome P450 isoenzymes oxidize eugenol to a reactive quinone methide intermediate, which covalently binds to proteins or conjugates with glutathione.[19] These reactive intermediates can cause necrosis of hepatic cells. In animal models, depletion of glutathione prior to the administration of eugenol causes substantial, dose-dependent liver damage, whereas repletion of glutathione stores reduces the hepatotoxicity.[20]

DOSE RESPONSE

The estimated acceptable daily oral intake of eugenol is 2.5 mg/kg.[21] Case reports associate the accidental ingestion of 5–10 mL (5–10 g; density = 1.04 g/mL) of clove oil by infants and young children with the development of serious toxicity including seizures, coma, metabolic acidosis, hepatic failure, and disseminated intravascular coagulation (DIC).[22,23] The typical kretek smoker inhales about 7 mg eugenol per cigarette.

TOXICOKINETICS

There are few human data on the pharmacokinetics of eugenol, the active ingredient in clove oil. Animal studies suggest that the lungs absorb minor amounts of eugenol after inhalation of smoke from clove cigarettes.[24] *In vitro* studies of rat hepatocytes suggest that eugenol undergoes substantial biotransformation, primarily by the formation of sulfate, glucuronic acid, and glutathione conjugates.[25] The major metabolite formed in these studies was the glucuronic acid conjugate. Side-chain epoxidation is a minor metabolic pathway observed in these *in vitro* studies.[26,27]

CLINICAL RESPONSE

Acute Effects

Case reports associate the accidental ingestion of clove oil by infants with the development of vomiting, pulmonary aspiration, and central nervous system depression.[28] Patients usually recover without sequelae with timely supportive care. Additional case reports suggest that the ingestion of clove oil in young children can cause hepatorenal failure including hypoprothrombinemia, elevated serum hepatic aminotransferases, seizures, and metabolic acidosis.[23] The intravenous injection of an unknown amount of clove oil produced noncardiogenic pulmonary edema in a 32-year-old woman, manifest by bilateral interstitial and alveolar infiltrates without evidence of cardiac insufficiency.[29] She did not

require intubation and she recovered without obvious sequelae.

Case reports associated the development of acute, severe respiratory symptoms in a few susceptible individuals with the recent use of clove cigarettes.[3] Frequently, these individuals had prodromal respiratory infections. These respiratory effects included hemoptysis, hemorrhagic and nonhemorrhagic pulmonary edema, pleural effusions, respiratory insufficiency, aspiration pneumonia, pulmonary infiltrates, and bronchospasm. However, the details of these case reports are not well documented, and there are limited new data on clove cigarette-associated respiratory distress since the middle 1980s.

Chronic Effects

Eugenol and clove leaf oil are weak sensitizers for the induction of allergic contact dermatitis.[30] Only one case of induced hypersensitivity and one case of preexisting hypersensitivity to eugenol were detected in patch test data from 11,632 subjects exposed to consumer products containing eugenol or clove leaf oil in concentrations up to 2.5%.[31] These cases of sensitization involved prolonged contact (i.e., 1–2 weeks) with dental products containing eugenol. Although rare, case reports associate the development of allergic reactions with the use of clove leaf oil. Stomatitis and intraoral ulceration can occur in sensitized individuals when exposed to clove oil in personal products, such as mouthwash.[32] Rarely, systemic reactions (e.g., urticaria) occur following the use of clove oil in dental products.[33,34]

The effects of long-term smoking of clove cigarettes are not well defined. There are limited data on the carcinogenicity of eugenol. The administration of eugenol to laboratory animals does not consistently produce tumors across animal species and gender. There is an absence of epidemiological data, and the IARC lists eugenol in Group 3 (not classifiable as to carcinogenicity).[2] *In vitro* test results for DNA damage following exposure to eugenol are inconsistent.[2] The US National Toxicology Program does not list eugenol as a compound reasonably anticipated to cause cancer.

DIAGNOSTIC TESTING

Analytical Methods

Eugenol is the principal active ingredient in clove oil, accounting for up to 80–85% of the product. Methods for the detection of eugenol in clove buds or clove oil include gas chromatography with flame ionization (GC/FID)[35] or gas chromatography/mass spectrometry (GC/MS). Micellar electrokinetic capillary electrophoresis with diode array detection is an alternative to gas chromatography that allows rapid separation and quantitation of eugenol and related compounds.[10] The limits of detection and quantitation for eugenol by this method are about 1 μg/mL and 3 μg/mL, respectively.

Biomarkers

The presence of eugenol helps confirm exposure, but there are few data correlating blood eugenol concentrations with clinical effects. Clove oil is not a unique source of eugenol; therefore, the presence of eugenol does not necessarily indicate exposure to clove oil or clove bud extracts.

Abnormalities

Laboratory abnormalities associated with case reports of acute clove oil poisoning include metabolic acidosis, elevated serum hepatic aminotransferases, hypoprothrombinemia, disseminated intravascular coagulation, and severe hypoglycemia.

TREATMENT

Stabilization

Patients with exposure to clove oil should be carefully evaluated for respiratory insufficiency and aspiration pneumonia with pulse oximetry and chest x-ray, particularly in the presence of altered consciousness. The analgesic properties of eugenol in clove oil may predispose these patients to aspiration pneumonia by decreasing the responsiveness of the gag reflex as a result of these local anesthetic effects. Severe hypoglycemia occasionally complicates the course of clove oil intoxication and all patients should be evaluated with a rapid blood glucose test. Severe hypoglycemia can occur during the first 8 hours after ingestion and before laboratory evidence of fulminant hepatic failure.[22] During severe intoxication, disseminated intravascular coagulation can develop despite the lack of clinical evidence of fulminant hepatic failure. These patients should be evaluated with a complete blood count (CBC), platelet count, prothrombin time (PT), partial thromboplastin time, D-dimer, and fibrin split products, as well as serum hepatic aminotransferases. The use of heparin for the treatment of DIC is controversial.

Antidote

There are few clinical data on the use of *N*-acetylcysteine for the treatment of hepatic failure associated with the ingestion of clove oil by children. Based on animal

data, there is a theoretical basis for the use of *N*-acetylcysteine for the glutathione depletion and hepatic necrosis present in animals receiving eugenol.[20] Several case reports document improvement in hepatic function after the use of intravenous *N*-acetylcysteine,[23,36] but lack of data on the natural course of hepatic failure from clove oil intoxication limit determination of the efficacy of *N*-acetylcysteine in this setting. Treatment in these case reports involved the use of the standard doses of intravenous *N*-acetylcysteine, similar to the treatment of acetaminophen hepatotoxicity.

Supplemental Care

Patients hospitalized for serious clove oil poisoning should be monitored closely for hepatorenal function, hypoglycemia, hypophosphatemia, metabolic acidosis, and electrolyte imbalance. Baseline blood tests for hospitalized patients include CBC, PT, and serum chemistries including hepatic aminotransferase, bilirubin, glucose, electrolytes, and creatinine. Hepatorenal function should be monitored daily for 3 days until a clear pattern of improvement in these serum tests occurs. Typically, a rise in PT and unconjugated bilirubin concentrations are the earliest biochemical markers of hepatotoxicity; these abnormalities usually occur before an elevation of serum hepatic aminotransferases. Bedside glucose monitoring is necessary several times daily in patients with fulminant hepatic failure.

The efficacy of vitamin K_1 for elevation of the prothrombin time during fulminant hepatic failure is unclear. Fresh frozen plasma (rarely, recombinant human factor VIIa) should be used for evidence of current bleeding or prophylactically for invasive procedures.[37] Prophylactic correction of coagulopathy in a nonbleeding patient is not usually recommended. Serial hemoglobin and stool guaiac tests should be followed for evidence of gastrointestinal bleeding. The administration of proton pump inhibitors (e.g., omeprazole) should be administered to reduce the risk of gastrointestinal hemorrhage. Cerebral edema is the major cause of death following the development of hepatic encephalopathy, and treatment includes mannitol, elevation of the head to 10–20 degrees, adjustment of ventilator settings, and fluid restriction. Epidural intracranial pressure monitoring is usually necessary to guide treatment of patients with grade 3–4 hepatic encephalopathy, and early transfer to a liver transplant center should be considered for these patients.

Chapter 60

COLOCYNTH
[*Citrullus colocynthis* (L.) Schrad.]

HISTORY

Colocynth is an ancient purgative, which was mentioned in the Ebers papyrus from 1500 BC, in the Bible (II Kings 4:38–41), and in Dioscorides' writings. Egyptian physicians used this plant as a strong purgative. The Arab medical writer, Mesue, listed the use of two colocynth preparations, trochisi alhandal and electuarium majus hamech, in *The Pharmacopoea Augustana* of 1581.[1] In the 1800s, colocynth was listed in every issue of the *US Pharmacopeia*. The toxicity of colocynth was also well-known to medieval physicians, who recognized the occurrence of hemorrhagic ulcers in the intestines following the impaction of colocynth seeds.[2] In the middle 19th century, a fatal case of severe vomiting and diarrhea was associated with the use of colocynth.[3] Fatalities have been associated with the use of colocynth as an abortifacient.[4]

BOTANICAL DESCRIPTION

Common Name: Bitter Apple, Bitter Cucumber, Bitter Gourd, Egusi, Wild Watermelon

Scientific Name: *Citrullus colocynthis* (L.) Schrad.

Botanical Family: Cucurbitaceae (melon)

Physical Description: This annual vine has slender, hairy stems, which develop from a large, perennial fleshy root. The large (5–10 cm/~2–4 in.), obtuse, hairy, triangular leaves have long petioles and are similar in appearance to watermelon leaves. Long (4–10 cm/1.5-4 in.), pedunculated, solitary yellow flowers produce smooth, globular fruit with a thick yellow rind and a light, spongy pulp filled with numerous seeds.

Distribution and Ecology: This plant is indigenous to desert and semiarid areas of Africa, Western Asia, and the Mediterranean region. Arabs introduced this plant to Spain and Cyprus.

EXPOSURE

This extremely bitter purgative is not commonly available as an herbal preparation. The fruits and, in particular, the pulp of this plant are well-known natural cathartics since ancient times. Colocynth is one of several herbs used for the treatment of hypertension and diabetes mellitus in Morocco.[5,6] The leaves of this herb are used to treat asthma and jaundice, whereas the root is a traditional treatment for amenorrhea, breast inflammation, arthralgias, and ophthalmic diseases. Other medicinal uses include the treatment of seizures, tuberculosis, syphilis, and parasitic infections. The use of colocynth as a cathartic is not recommended by the German Commission E because of concern about adverse effects including severe gastrointestinal irritation, hemorrhagic diarrhea, renal dysfunction, and cystitis. Cucurbitacin I is a tetracyclic triterpenoid present in this plant that is a strong inhibitor of the janus kinase 2/signal transducer and an activator of transcription 3 (JAK2/STAT3) signaling pathway. STAT3 is a common oncogenic signaling pathway, and cucurbitacin compounds are potential chemotherapeutic agents.[7]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

PRINCIPAL INGREDIENTS

Ethanol extracts of colocynth and other members of the Cucurbitaceae family contain highly oxygenated tetracyclic triterpene compounds called cucurbitacins.[8] These bitter compounds possess cytotoxic properties.[9] Although originally isolated from species from this family, cucurbitacin compounds occur in a variety of plant families (e.g., Brassicaceae, Begoniaceae, Datiscaceae, Desfontainiaceae, Elaeocarpaceae, Rubiaceae, Rosaceae, Sterculiaceae, Thymelaeaceae), as well as several genera of mushroom (*Russula*, *Hebeloma*). Figure 60.1 displays the chemical structure of cucurbitacin I ($C_{30}H_{42}O_7$, CAS RN:2222-07-3). There are a variety of cucurbitacin compounds including cucurbitacin A, B, C, D, E, F, I, L and glucosides,[10] colocynthosides A and B, T, 23-dihydrocucurbitacin F, 24-dihydrocucurbitacin F, hexanorcucurbitacin F, and acetylated derivatives. However, not all of these compounds has been isolated from this plant species.[11,12] There are few data to determine which cucurbitacin compounds are the active or toxic ingredients present in colocynth.

DOSE RESPONSE

There are few data on the dose response of the toxin in colocynth, in part because of the lack of identification of the specific compound associated with the toxic colitis. The older medical literature suggests that 0.6–1 g of colocynth extract can produce bloody diarrhea.[13]

TOXICOKINETICS

There are few data on the toxicokinetics of cucurbitacin compounds. *In vitro* studies suggest that colocynth inhibits CYP1A-, CYP2B-, and CYP3A-dependent reactions, but there are few data to determine the clinical importance of these potential reactions.[14]

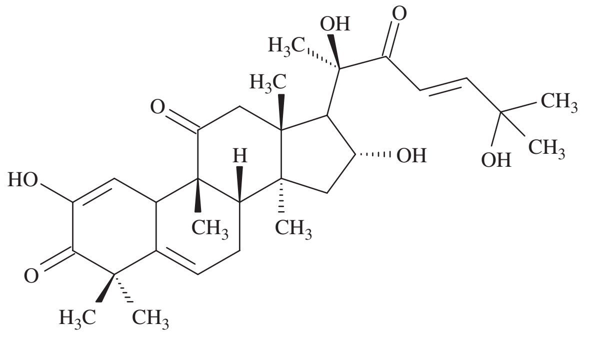

FIGURE 60.1. Chemical structure of cucurbitacin I.

CLINICAL RESPONSE

Case reports associate the use of extracts of *Citrullus colocynthis* with the development of bloody diarrhea, vomiting, colicky abdominal pain, and dehydration.[15] Pathological lesions primarily involve edema, erythema, superficial erosions and inflammatory exudates of the mucosa in the sigmoid and descending colon. Ulcerations and pseudopolyps are unusual features of this toxic colitis. Symptoms typically resolve within 3–6 days, and the pathological lesions resolve within 14 days without sequelae.[13]

DIAGNOSTIC TESTING

Biomarkers of the toxicity associated with colocynth currently are not available. Sensitive analytical methods are available for the detection of cucurbitacin compounds. The limit of quantitation of cucurbitacin I in plasma using liquid chromatography/mass spectrometry is about 10 ng/mL.[16]

TREATMENT

Treatment is supportive. Gut decontamination is usually unnecessary because of the diarrhea and vomiting associated with colocynth toxicity. Patients should be evaluated for fluid and electrolyte imbalance and any deficiencies should be corrected with fluid and/or electrolytes infusions.

Chapter 61

COLTSFOOT
(*Tussilago farfara* L.)

HISTORY

Herbal preparations of coltsfoot are traditional treatments for cough and bronchitis.

BOTANICAL DESCRIPTION

The development of veno-occlusive disease following the ingestion of teas brewed from pyrrolizidine-containing plants may occur as a result of the misidentification of coltsfoot for pyrrolizidine-containing plants (e.g., *Adenostyles alliariae* A. Kern.) or some *Petasites* species [*P. vitifolius* Greene (pro sp.), *P. frigidus* Fries].[1]

Common Name: Coltsfoot, Colts Foot

Scientific Name: *Tussilago farfara* L.

Botanical Family: Asteraceae (sunflowers or tournesol family)

Physical Description: This perennial herbaceous plant has a creeping rhizome and long runners. The basal leaves are hear-shaped and slightly toothed with width of up to 15 cm (~10 in.). The top of the mature leaves are glossy and dark green, whereas the underside is covered with gray, felt-like hairs. Young leaves have dense felt on both sides. Several, white woolly flowering stalks arise directly from the rootstock in the spring. Each stalk bears a single yellow flower head consisting of tubular disk flowers at the center surrounded by ray flowers. The appearance of the ripe seed head is similar to the dandelion. After the flowers appear, leaves develop on long erect stalks arising directly from the rootstock.

Distribution and Ecology: This plant is a common, invasive weed that grows in heavy clay soils throughout Britain, Europe, North Africa, Asia, and sporadically in the United States. This plant inhabits wet areas, such as creek beds and meadows.

EXPOSURE

The flower of coltsfoot (kuan donghua) is used as a traditional treatment for respiratory problems, such as bronchitis, asthma, and cough. Other traditional uses include the treatment of eye irritation, menstrual irregularities, varicose veins, wounds, and burns.[2] Coltsfoot contains pyrrolizidine alkaloids, which are potentially carcinogenic. The German Commission E limits the concentration of pyrrolizidine alkaloids in herbal products. However, the listing of pyrrolizidine alkaloids is not required in the United States.

PRINCIPAL INGREDIENTS

Chemical Composition

Extracts of coltsfoot contain pyrrolizidine alkaloids, primarily senkirkine (CAS RN: 2318-18-5) in an amount of approximately 0.15 g/kg.[3] Figure 61.1 displays the chemical structure of senkirkine ($C_{19}H_{27}NO_6$). The flowers and a decoction from the boiling of 5 g coltsfoot leaves in water contained about 0.45 ppm senkirkine as

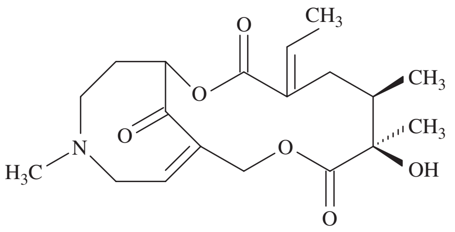

FIGURE 61.1. Chemical structure of the pyrrolizidine alkaloid, senkirkine.

measured by cation-exchange solid-phase extraction and ion-pair high performance liquid chromatography.[4] Senecionine (CAS RN: 130-01-8) was not detected in these samples by this method. Analysis of dried, young flowers of coltsfoot demonstrated a pyrrolizidine content (i.e., primarily senkirkine) of about 0.015% dry weight.[5] The methylene chloride extract of the flower buds from coltsfoot contains a vasoactive substance, tussilagone (L–652,469), which produces dose-dependent pressor effect in anesthetized animals.[6]

Physiochemical Properties

Tussilagone ($C_{23}H_{34}O_5$, CAS RN: 104012-37-5) is a sesquiterpene compound that inhibits the binding of platelet-activating factor to platelet membranes and the specific binding of experimental Ca^{2+} channel blockers in the cardiac sarcolemmal vesicles of rats.[7] This compound has low polarity and low water solubility.[6] Additionally, the ethyl acetate fraction of flower buds from *Tussilago farfara* inhibited lipid peroxidation and arachidonic acid metabolism, as well as demonstrating antioxidant properties.[8] Senkirkine is a hepatotoxic pyrrolizidine alkaloid present in variable amounts in traditional herbal medicines derived from coltsfoot.

DOSE RESPONSE

There are limited data on the dose response of the active ingredients in coltsfoot. For an ultrasonically prepared emulsion of soy bean phospholipid containing tussilagone, the intravenous LD_{50} and LD_{10} in mice was 28.9 ± 1.8 mg/kg and 25.3 ± 2.0 mg/kg, respectively.[6]

TOXICOKINETICS

There are inadequate data to determine the toxicokinetics of tussilagone in humans.

CLINICAL RESPONSE

There is limited evidence for the carcinogenicity of both senkirkine and coltsfoot (*Tussilago farfara*) in experimental animals. A small lifetime study of rats fed up to 32% coltsfoot in their diet detected a dose-related increase in hemangioendothelial sarcomas of the liver.[5] Histological examination of the livers demonstrated centrilobular necrosis, destruction of hepatocytes, intrahepatic bile proliferation, and cirrhosis even in the absence of liver tumors. Twenty rats received intraperitoneal injections of freshly prepared senkirkine at a dose of 10% of the median lethal dose twice weekly for 4 weeks and then once weekly for 52 weeks.[9] Over the lifetime of these rats, 9 of 20 rats developed liver adenomas, whereas no tumors developed in control rats receiving intraperitoneal injections of saline at the same time intervals. In the absence of epidemiological data, the International Agency for Research on Cancer listed senkirkine as an agent not classifiable as to its carcinogenicity to humans (Group 3).[10]

DIAGNOSTIC TESTING

Limits of detection and quantitation for the pyrrolizidine alkaloid, senkirkine, were 0.07 µg/mL and 0.20 µg/mL, respectively, when measured by cation-exchange solid-phase extraction and ion-pair high performance liquid chromatography.[4] Micellar electrokinetic chromatography is a simple, rapid method for the separation and determination of toxic pyrrolizidine alkaloids (senkirkine, senecionine, retrorsine, seneciphylline) potentially present in the traditional Chinese herbal medicines (kuan donghua) derived from coltsfoot.[11]

TREATMENT

Treatment is supportive. Gut decontamination measures are usually unnecessary.

Chapter 62

COMFREY and OTHER PYRROLIZIDINE-CONTAINING PLANTS

HISTORY

Hepatotoxic, pyrrolizidine-containing herbs are present in several plant families, and the consumption of these plants as teas or contaminates of cereal have caused epidemics of hepatic veno-occlusive disease in various countries throughout the world.[1] In 1920, Wilmot and Robertson described liver cirrhosis associated with the ingestion of *Senecio* species in South Africa.[2] Cases of pyrrolizidine alkaloid intoxication are sporadic in the developed Western countries, whereas epidemics of veno-occlusive disease occur in underdeveloped countries where pyrrolizidine alkaloids contaminate foodstuffs. During periods of famine in Afghanistan[3] and in southern Tajikistan,[4] the consumption of bread contaminated by seeds from *Heliotropium lasiocarpum* Fisch. & C. A. Mey. caused an outbreak of hepatic veno-occlusive disease. In India, the ingestion of bread contaminated by *Crotalaria* seeds produced an epidemic of veno-occlusive liver disease.[5] Case reports from India also associated the use of pyrrolizidine-containing herbs (*Heliotropium lasiocarpum*) with the development of veno-occlusive disease and hepatic failure.[6] The consumption of *Echium* and *Heliotropium* species by grazing animals also produces liver toxicity and death.[7] In Jamaica, the ingestion of bush teas brewed from local *Crotalaria* species caused veno-occlusive disease in the 1950s.[8]

BOTANICAL DESCRIPTION

There are over 350 pyrrolizidine alkaloid-containing plants in more than 6,000 plant species from the Boraginaceae, Asteraceae (Compositae), Convolvulaceae, Fabaceae, Hyacinthaceae, Lamiaceae, and Moraceae families.[9,10] Most of these plant species are invasive weeds that produce toxicity in animals consuming contaminated feeds and grains. Case reports of human toxicity from pyrrolizidine-containing plants are relatively uncommon compared with animal toxicity. Pyrrolizidine-containing plants involved in human toxicity include *Adenostyles alliariae* A. Kern., *Symphytum officinale* L., and *Tussilago farfara* L., as well as species from the genera *Senecio*, *Crotalaria*, and *Heliotropium.*[11]

Asteraceae (Sunflower)

There are approximately 3,000 species of *Senecio* plants distributed worldwide with over 30 species associated with pyrrolizidine toxicity in grazing animals.[12] One of the most common species is *S. jacobaea*.

Common Name: Tansy Ragwort, Stinking Willie

Scientific Name: *Senecio jacobaea* L.

Physical Description: This tall (up to 5 ft/~1.5 m), erect perennial weed has a tall, flowering stalk in the spring. Composite yellow heads produce thousands of seeds. The leaves are pinnate varying up to 9–10 in. (~23–25 cm) in length. Accidental exposure to tansy ragwort may result from the confusion of this plant with the herb tansy (*Tanacetum vulgare* L.).

Distribution and Ecology: *Senecio jacobaea* is a native plant in the British Isles, but this species has been introduced into Western Europe, North

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

America (the West, the Northeast, Michigan, Illinois), New Zealand, Australia, and South Africa.

Common Name: Threadleaf Groundsel, Threadleaf Ragwort, Wooly Groundsel

Scientific Name: *Senecio flaccidus* Less. (*Senecio douglasii* species *longilobus*)

Physical Description: This low, perennial, woody shrub grows to 2 ft (0.6 m) in height. A white wooly pubescence covers the large, pinnate leaves. The composite heads contain numerous flat terminal clusters with yellow rays.

Distribution and Ecology: *Senecio flaccidus* is a native shrub of the southwestern United States.

Boraginaceae (Borage)

Echium species are hardy annual and biennial plants that possess erect, hairy stems and ovate to lanceolate, green leaves. *Heliotropium europaeum* L. (European heliotrope) is an annual plant that contains gray-green, oval leaves covered with short, white hairs and prominent veins. Heliotrope seeds are approximately 2 mm (~0.08 in.) long, occurring in groups of four single-seeded nutlets.

Common Name: Wild or Common Comfrey, Comfrey, Blackwort, Borraja, Bourrache, Buyuk Karakafesotu, Consoude, Consuelda, Hirehari-So, Liane Chique

Scientific Name: *Symphytum officinale* L.

Physical Description: This invasive perennial weed grows up to 5 feet (~1.5 m) in height and possesses long, hairy leaves with narrow ends, deep roots, and yellowish to red-violet flowers. Misidentification of this plant occurs with foxglove (*Digitalis* spp.), particularly when comfrey is not flowering.

Distribution and Ecology: *Symphytum* species inhabit areas in Europe, North America, Siberia, and Asia. Wild or common comfrey is native to England and this plant can be found throughout most of Europe, central Asia, western Siberia, and the United States. *Symphytum officinale* (common comfrey) is an invasive weed introduced into the western, midwestern, and northeastern United States.

Common Name: Russian Comfrey, Caucasian Comfrey, Blue Comfrey, Quaker Comfrey

Scientific Name: *Symphytum x uplandicum* Nyman (*S. asperum X officinale*)

Physical Description: This plant is a hybrid between the English species, *Symphytum officinale*, and the SW Asian species, *Symphytum asperum*. This hybrid is a tall, rank, herbaceous perennial with a poorly developed wing and blue, violet or purple tubular flowers. The poorly developed stem wing is the most characteristic feature distinguishing this hybrid from *S. officinale*.

Distribution and Ecology: This species is a natural hybrid of *S. officinale* L. (common comfrey) and *S. asperum* Lepechin (prickly comfrey) that was introduced into England from Russia in the 1800s and into Canada and the United States in the 1950s. Most comfrey plants in the United States derive from this hybrid. This plant easily naturalizes to waste areas and roadsides.

Fabaceae (Leguminoseae)

Most *Crotalaria* species are perennial branched legumes that reach up to 3 ft (~0.9 m) in height. The simple 1–2 in. (~2.5–5.0 cm) leaves contain short pubescence on both sides. The small yellow flowers produce 1–2 in. (~2.5–5.0 cm) seed pods that contain brown, kidney-shaped, 2–3 mm (~0.10 in.) seeds that rattle inside the pod when dried. The common name for these species is "rattle pod."

Common Name: Common Houndstongue, Gypsy-Flower, Gypsy Flower, Hound's Tongue, Houndstongue

Scientific Name: *Cynoglossum officinale* L.

Physical Description: An annual or biennial plant that forms rosettes the first year and regrows from a taproot the following year to produce a flowering stalk up to 3 ft (~1 m) in height and 2–3 in. (~5–8 cm) long, brown nutlets.

Distribution and Ecology: *Cynoglossum officinale* (hound's tongue) is an invasive weed in the United States that is native to Europe.

EXPOSURE

Most pyrrolizidine-containing plants are invasive weeds that may contaminate the feed of grazing animals. In Western Europe, comfrey is a traditional herb for the treatment of inflammatory conditions (gout, arthritis, thrombophlebitis), skin wounds (bruises, fungal infections, ulcers, fractures, strains), varicose veins, oral lesions (gargle), bronchitis, allergies, gastritis, gastroduodenal ulcers, and diarrhea.[13,14] Russian comfrey is consumed as salad and as a tea made from the powdered root.[15] The internal use of comfrey is not approved by US, Canadian, or South African health agencies. The

German Commission E limits the use of comfrey to external applications.

PRINCIPAL INGREDIENTS

Chemical Composition

Most pyrrolizidine-containing plants contain mixtures of alkaloids with varying potency and concentrations. In *Senecio* species, senecionine *N*-oxides form in the roots. These compounds are transported to the above-ground plant organs via the phloem where pyrrolizidine alkaloids form in a species-specific pattern.[16] Common patterns of pyrrolizidine alkaloids include jacobine, erucifoline, and mixed or senecionine types.[17] Typically, the pyrrolizidine content is highest in the roots with smaller concentrations in the leaves, particularly older leaves.[18] A study of *Senecio jacobaea* indicated that the pyrrolizidine content on the surface of the leaves was substantially higher than the alkaloids in the interior of the leaf.[19] In addition to pyrrolizidine alkaloids, comfrey contains allantoin, polyphenols, amino acids, phytosterols, saccharides, triterpenoids, and mucilage.[20] Commercial honey and honey samples containing two grains or less of Ragwort pollen per gram of honey do not usually contain detectable amounts of pyrrolizidine alkaloids.[21] Honey samples collected in late July and August contained Ragwort pollen at 15–21 grains/g, and these samples had total pyrrolizidine alkaloid concentrations of 0.011–0.056 mg/kg. The major alkaloids were jacobine, jacozine, seneciophylline, and senecionine with jacoline being a minor constituent.

Asteraceae

The pyrrolizine content in *Senecio jacobaea* is approximately 0.2% dry weight.[9] *S. flaccidus (S. douglasii* subsp. *longilobus)* contains four pyrrolizidine alkaloids comprising up to about 2% dry weight with retrorsine being the major alkaloid. Unlike most other *Senecio* species, Riddell's ragwort (*Senecio riddellii* Torr. & Gray) contains primarily one alkaloid (i.e., riddelliine) at concentrations ranging up to 18% dry weight.[9] Senkirkine is a constituent of numerous *Senecio* species including *Senecio kirkii* Hook. F. ex Kirk, *Senecio rodriguezii* Willk. ex Rodr., and *Senecio jacobaea* L. as well as *Tussilago farfara* L. (coltsfoot). The main pyrrolizidine alkaloids in *S. rodriguezii* are retronecine-based (seneciphylline, seneciphyllinine) and otonecine-based (senkirkine, acetylsenkirkine) alkaloids, whereas the main alkaloid in *S. leucanthemifolius* Poiret is integerrimine.[22] *Psacalium decompositum* (Gray) H.E. Robins. & Brett. (desert indianbush, matarique) is an indigenous herb of northern Mexico and southwestern United States that contains at least seven pyrrolizidine alkaloids.[23]

Boraginaceae

The pyrrolizidine content of *Symphytum* species varies with plant part, season, natural biological variation, and species. Pyrrolizidine alkaloids in common comfrey (*S. officinale*) include intermedine, acetylintermedine, lycopsamine, acetyllycopsamine, echimidine, symviridine, and symphytine (Figure 62.1). Small young leaves early in the season possess higher total alkaloid content than older leaves, and the roots contain greater concentrations of total pyrrolizidine alkaloids than above-ground plant parts.[24] In a study of commercial samples of common comfrey (*S. officinale*), analysis of the total pyrrolizidine alkaloid content demonstrated values ranging from 1,380–8,320 µg/g root compared with 15–55 µg/g leaf.[25] The major pyrrolizidine alkaloids were symphytine and symlandine along with lesser concentrations of echimidine, lycopsamine, and acetyl lycopsamine. Analysis of comfrey tablets indicated that total alkaloid concentrations are similar to the alkaloid content of comfrey roots. The total alkaloid content of fresh leaves from Russian comfrey (*Symphytum x uplandicum*) ranges from about 0.01–0.15% with lycopsamine and echimidine accounting for a majority of the eight pyrrolizidine alkaloids.[26] In general, the concentration of echimidine in *Symphytum x uplandicum* and *Symphytum asperum* Lepechin (prickly comfrey) are substantially higher than *Symphytum officinale*.[27]

FIGURE 62.1. Chemical structures of pyrrolizidine alkaloids in common comfrey (*S. officinale*).

FABACEAE

Cynoglossum officinale (hound's tongue) contains four pyrrolizidine alkaloids at concentrations up to 2.2% dry weight with heliosupine being the most abundant.[9] The principal toxic alkaloids of *Heliotropium* species include heliotrine, lasiocarpine, and their *N*-oxides.

Physiochemical Properties

In general, naturally occurring pyrrolizidine alkaloids are esterified 8-membered necine compounds. These alkaloids are heterocyclic compounds composed of esters of basic alcohols (necine bases) connected to necic acid (C_5–C_{10} chain acids) via hydroxy groups at positions 7 and 9 by an ester function. Figure 62.2 demonstrates the basic structure of pyrrolizidine alkaloids. This diverse class of naturally occurring secondary metabolites include macrocyclic diesters (monocrotaline, retrorsine, senecionine, petasitenine), open diesters (lasiocarpine), monoesters (heliotrine), and necine bases.[28] Alkaline hydrolysis produces alkanolamines (necines) and necic acids. Total alkaloid content of these compounds includes both the free bases and the *N*-oxide forms. These compounds are colorless, optically active alkamine esters that are chemically stable and variably water soluble. Water-soluble salts of pyrrolizidine compounds include nitrates, sulfates, and chlorides. Drying and heating during food processing does not affect the toxicity of *Heliotropium* alkaloids.

Mechanism of Toxicity

Based on animal studies, the toxicity of pyrrolizidine alkaloids varies with individual compounds and animal species (e.g., pigs, chickens, and rats are much more sensitive than mice and sheep). In rodent studies, the most toxic pyrrolizidine compounds are macrocyclic diesters with heliotridine esters being 2–4 times more toxic than retronecine esters.[29] The primary toxicity of pyrrolizidine alkaloids is a sinusoidal-obstruction syndrome similar to the hepatotoxicity associated with bone marrow transplantation. During the acute phase of pyrrolizidine-induced hepatotoxicity, sinusoidal endothelial cells, central venular endothelial cells, and hepatic parenchymal cells undergo degeneration followed by a subacute phase consisting of fibrotic occlusion of central and sublobular veins along with sinusoidal fibrosis.[30] Most hepatotoxic pyrrolizidine are cyclic diesters (e.g., retrorsine, senecionine), and the structural requirement for pyrrolizidine toxicity is the presence of an unsaturated pyrrolizidine ring. Esterification of necine compounds containing a double bond in the 1,2 position causes the formation of toxic alkaloids.[31] All toxic pyrrolizidine alkaloids are ester derivatives of 1-hydroxymethyl-1,2-dehydropyrrolizidine with variable esterification at positions C1 and C7.[11] Reactive dehydroalkaloid (pyrrolic) intermediates resulting from the metabolism of pyrrolizidine compounds are potent electrophiles that can cross-link with cellular components (e.g., DNA, proteins, amino acids, glutathione).[32] These adducts are responsible for local cytotoxic and antimitotic effects.[33] These reactive pyrroles produce nonthrombolytic obliteration of small hepatic veins that may progress to cirrhosis and liver failure. Dehydroalkaloid intermediates with longer half-lives (e.g., retrosine, seneciphylline) may cause damage in the lungs (e.g., pulmonary endothelial cells, type II pneumocytes) similar to monocrotaline and fulvine.[34] Animal studies indicate that the hepatotoxic potential of rosmarinine, retronecine, and senaetnine is relatively low.[35]

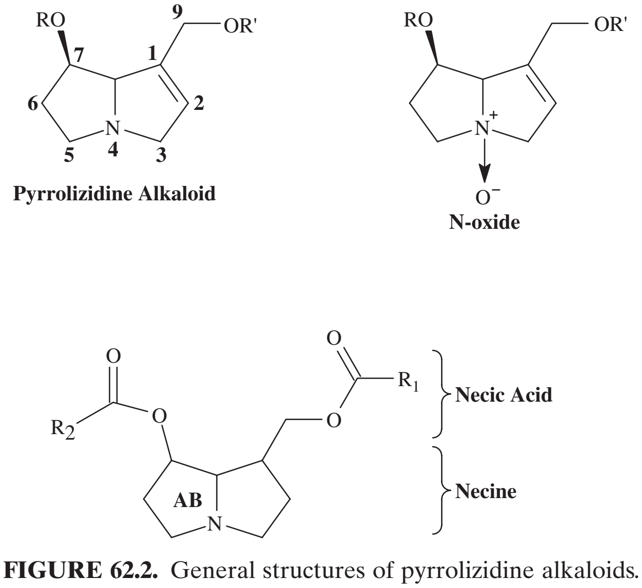

FIGURE 62.2. General structures of pyrrolizidine alkaloids.

Upon metabolic activation, pyrrolizidine alkaloids exhibit a variety of genotoxic properties including DNA binding, DNA-protein cross-linking, sister chromatid exchange, chromosomal aberrations, and carcinogenicity. The most potent genotoxic pyrrolizidine alkaloids are macrocyclic diesters (retronecine, heliotridine, otonecine).[36]

DOSE RESPONSE

Medicinal Use

Typical daily herbal doses of comfrey leaf and root are about 5–30 g and 0.5–10 g, respectively.[37] There are no specific indications for the internal use of pyrrolizidine alkaloids. The German Federal Health Department limits the daily external application of total pyrrolizidine alkaloids to 0.1 μg for no more than 6 weeks per

year. Because of potential toxicity, the internal use of pyrrolizidine-containing compounds is not recommended.

Toxicity

Due of the wide variability in total pyrrolizidine content in various plant species and interindividual variation in susceptibility, the dose response relationship for pyrrolizidine alkaloids is not well defined. Because the free base and the *N*-oxide forms of pyrrolizidine alkaloids demonstrate similar toxicity, the total alkaloid content of a plant or extract probably correlates reasonably well to severity of the hepatoxicity.[38] The daily consumption of comfrey containing an estimated 15 µg total pyrrolizidine alkaloids/kg body weight (total estimated minimal dose = 85 mg) over 6 months along with chamomile tea and vitamin supplements was associated with the development of veno-occlusive disease in a woman.[39] Three Chinese women developed fatal hepatic failure after ingesting an herbal tea containing pyrrolizidine alkaloids. The estimated mean cumulative dose of pyrrolizidine alkaloid base and *N*-oxide derivatives ingested prior to the onset of symptoms was 18 mg/kg.[40] A fourth woman, who ingested a total cumulative dose of 15 mg/kg, developed asymptomatic liver disease. During a famine, severe liver disease resulted from the daily ingestion of total pyrrolizidine alkaloids from *Heliotropium* alkaloids at an estimated dose of 30–40 µg/kg body weight.[3] An estimated dose of 70–147 mg of total pyrrolizidine alkaloids from *Senecio* tea (gordolobo yerba) was associated with liver cirrhosis in a 6-month-old infant.[41] The estimated daily ingestion of 60 µg total pyrrolizidine alkaloids (primarily seneciphylline)/kg over 15 months produced reversible veno-occlusive disease in an infant.[42] Children appear particularly susceptible to pyrrolizidine toxicity, but the specific dose response for the pediatric population has not been defined.

TOXICOKINETICS

Animal studies suggest that the percutaneous absorption of pyrrolizidine alkaloids is low (<0.5% of the applied dose).[43] Biotransformation of pyrrolizidine alkaloids involves *N*-oxidation to *N*-oxides, hydrolysis to free necic acid and necic bases, and dehydrogenation to toxic pyrroles (dehydroalkaloids).[44] Figure 62.3 displays the general biotransformation of pyrrolizidine alkaloids. The parent pyrrolizidine alkaloids are nontoxic, and the development of hepatic damage requires metabolism of the pyrrolizidine alkaloids by the cytochrome P450 oxidase system (e.g., CYP3A4, CYP2B6) to the hepatotoxic compounds, dehydropyrrolizidine alkaloids (pyrrolic esters).[45,46] These highly reactive compounds either form adducts with cell constituents or undergo further hydrolysis to dehydroamino alcohol compounds (pyrrolic alcohols). Detoxification involves *N*-oxidation of the pyrrolizidine alkaloid or conjugation of the pyrrole intermediate with glutathione.

The metabolic formation of reactive pyrrolic ester metabolites in humans occurs primarily through the actions of CYP3A and, to a lesser extent, CYP2B isoenzymes. Cleavage of pyrrolizidine alkaloids by nonspecific blood esterases produces necine compounds and

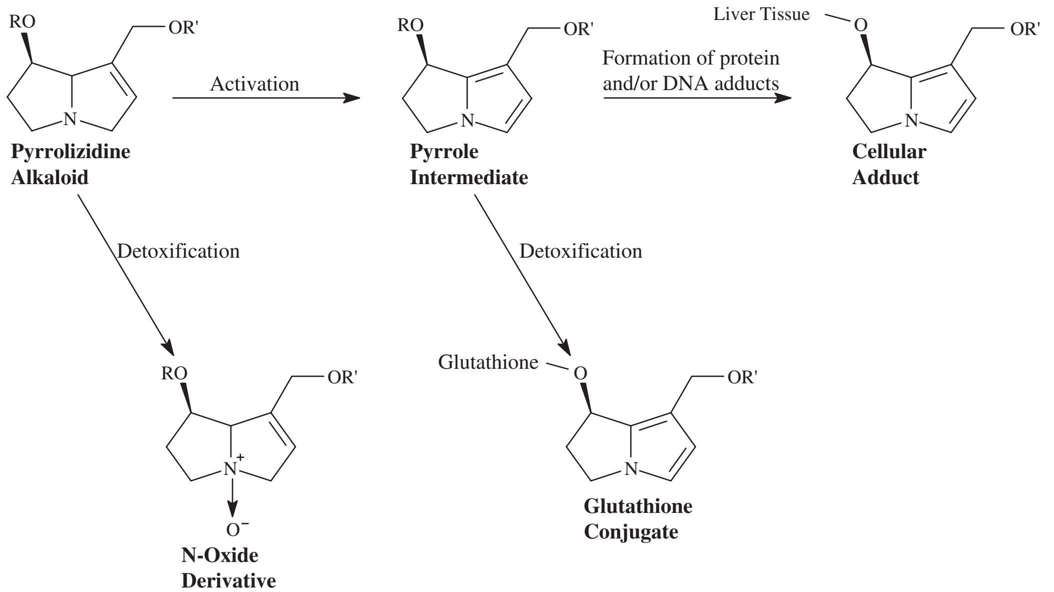

FIGURE 62.3. Activation and biotransformation of pyrrolizidine alkaloids (PA). Adapted from Rode D. Comfrey toxicity revisited. Trends Pharmacol Sci 2002;23:497.

necic acids, which ultimately appear in the urine as conjugates.[31] *In vitro* studies indicate that glutathione and *N*-acetylcysteine detoxify pyrrolizidine metabolites by forming water-soluble conjugates that are excreted by the kidney.[47] Animal studies indicate that the elimination of pyrrolizidine compounds is relatively rapid with most of the metabolites appearing in the urine within 24 hours after exposure.[48] Animal species vary substantially in their biotransformation of pyrrolizidine alkaloids to toxic metabolites.[15]

CLINICAL RESPONSE

Liver Toxicity

The clinical features of pyrrolizidine-induced veno-occlusive disease are similar to other diseases (Budd-Chiari syndrome, Reye's syndrome) that cause severe hepatic dysfunction with both an acute and chronic form of the disease.[49] Acute forms of veno-occlusive disease involve the rapid progression of hepatic necrosis, cirrhosis, portal hypertension, marked elevation of serum hepatic aminotransferases, and hepatic failure characterized clinically by vomiting, progressive hyperpnea, and encephalopathy.[50] The subacute form involves the gradual development of ascites, hepatomegaly, and gastrointestinal (GI) symptoms (abdominal pain, vomiting, diarrhea, pedal edema) that may resolve following the cessation of exposure to pyrrolizidine alkaloids.[42] Features of chronic forms of pyrrolizidine poisoning include the insidious onset of fatigue, right upper quadrant abdominal pain, anorexia, generalized weakness, weight loss, GI symptoms, ascites, hepatosplenomegaly, and progressive cirrhosis. Fever, jaundice, and bleeding are uncommon in this form of liver disease.[3] Prolonged pyrrolizidine alkaloid consumption can also cause pulmonary artery hypertension, leading to cor pulmonale and right ventricular hypertrophy. Other etiologies of veno-occlusive disease include methotrexate, azathioprine, radiotherapy, bone marrow transplantation, oral contraceptives, systemic lupus erythematosus, and alcoholic hepatitis.[9]

Carcinogenicity

The wide variety of pyrrolizidine compounds and the sparse carcinogenic testing of these compounds limit conclusions regarding the carcinogenic risk from ingesting comfrey and other plant materials containing pyrrolizidine compounds. The International Agency for Research on Cancer (IARC) lists lasiocarpine, riddelliine, and monocrotaline as possible human carcinogens (Group 2B), whereas retrorsine, hydroxysenkirkine, isatidine, jacobine, seneciphylline, and senkirkine are not classifiable as to carcinogenicity (Group 3).[51,52] Chronic rodent assays indicate that the consumption of dried leaves and roots of comfrey (*Symphytum officinale*) at doses of 1–16% of the total diet (dry weight/dry weight) produces an increased incidence of liver (adenomas, hemangioendothelial sarcomas) and urinary bladder tumors (papillomas, carcinomas).[53] The large doses of pyrrolizidine used in this study suggest that these compounds are weak carcinogens in rats. Although some pyrrolizidine alkaloids (e.g., symphytine, riddelliine) are positive in 2-year rodent studies,[54] there is no direct evidence that the ingestion of pyrrolizidine alkaloids causes cancer in humans.[55]

DIAGNOSTIC TESTING

Analytical Methods

Pyrrolizidine alkaloids can be extracted with classical methods (hot methanol, 95% ethanol).[11] *N*-oxides are more water soluble than the corresponding free bases; however, *N*-oxides are thermolabile. Colorimetry is a nonspecific, semiquantitative method for detecting pyrrolizidine alkaloids. The most sensitive and specific methods for the detection of pyrrolizidine compounds are liquid chromatography/mass spectrometry and gas chromatography/mass spectrometry (GC/MS). The coupling of liquid chromatography with electrospray ionization ion trap mass spectrometry allows the simultaneous analyses of these compounds and their corresponding *N*-oxides without the use of a reduction step required for GC/MS.[56,57] For pyrrolizidine compounds extracted from plant material, the use of gas chromatography-tandem mass spectrometry allows the analysis of toxic pyrrolizidine metabolites in blood samples at a detection limit of 2 μg/mL.[11] The use of a C_{18} column with a water-acetonitrile gradient as the mobile phase allowed the identification of pyrrolizidine alkaloids and their *N*-oxides as measured by liquid chromatography-ion trap mass spectrometry.[58]

Abnormalities

Liver biopsies of patients with veno-occlusive disease demonstrate histological changes of a centrilobular hemorrhagic congestion and necrosis affecting primarily zones II and III along with reticulin fibers within the lumen of central and sublobular veins. Fibrosis occurs predominately in the perivenular areas rather than the portal tracts.[59] Thickening of the venules produces a functional outflow obstruction and congestion. Liver angiography demonstrates narrowing of the lumen of the small hepatic veins along with nonhomogeneous filling of the hepatic sinusoids.[60] The main hepatic veins

and the portal veins typically remain patent. Electromicroscopy demonstrates the occurrence of hepatocyte blebs (clasmatosis) in sinusoidal borders, but these changes are not pathognomonic for pyrrolizidine-induced liver disease.[61] The hepatic lobular architecture usually remains intact until late in the course of the disease. Histological signs of inflammation are typically absent.[39]

Laboratory abnormalities associated with veno-occlusive disease include hypoglycemia, leukocytosis, mild hyperbilirubinemia (primarily indirect), variable increases of serum hepatic aminotransferase concentrations, thrombocytopenia, and hemolytic anemia. Ultrasound and imaging studies of the liver do not usually demonstrate significant abnormalities until portal hypertension becomes clinically significant.

TREATMENT

Management of veno-occlusive disease is supportive. Gut decontamination measures are usually unnecessary. There are no specific antidotes for pyrrolizidine-induced liver disease, and treatment is supportive. Patients hospitalized for serious pyrrolizidine-induced liver disease should be monitored closely for hepatorenal function, hypoglycemia, hypophosphatemia, metabolic acidosis, and electrolyte imbalance. Baseline blood tests for hospitalized patients include complete blood count, prothrombin time, and serum chemistries including hepatic aminotransferase, bilirubin, glucose, electrolytes, and creatinine. Hepatorenal function should be monitored daily for 3 days until a clear pattern of improvement in these serum tests occurs. Typically, a rise in prothrombin time and unconjugated bilirubin levels are the earliest biochemical markers of hepatotoxicity; these abnormalities usually occur before an elevation of serum hepatic aminotransferases. Bedside glucose monitoring is necessary several times daily in patients with fulminant hepatic failure.

The efficacy of vitamin K_1 for elevation of the prothrombin time during fulminant hepatic failure is unclear. Fresh frozen plasma (rarely, recombinant human factor VIIa) should be used for evidence of current bleeding or prophylactically for invasive procedures. Prophylactic correction of coagulopathy in a non-bleeding patient is not usually recommended. Serial hemoglobin and stool guaiac tests should be followed for evidence of GI bleeding. The administration of proton pump inhibitors (e.g., omeprazole) should be administered to reduce the risk of GI hemorrhage. Cerebral edema is the major cause of death following the development of hepatic encephalopathy, and treatment includes mannitol, elevation of the head to 10–20 degrees, adjustment of ventilator settings, and fluid restriction. Epidural intracranial pressure monitoring is usually necessary to guide treatment of patients with grade 3–4 hepatic encephalopathy. Hospitals without liver transplantation programs should transfer patients with fulminant hepatic failure as soon as possible to liver transplant centers because of the difficulty transferring patients with severe coagulopathy and cerebral edema. Orthotopic liver transplantation should be considered as a therapeutic option when severe liver failure occurs.

Chapter 63

CRANBERRY
(*Vaccinium macrocarpon* Aiton)

HISTORY

Although Native Americans introduced Europeans to cranberries, canned cranberry sauce did not become commercially available until the 1920s and cranberry juice appeared in US markets during the 1940s. The use of cranberry extracts to treat urinary tract infections dates back at least to the 19th century.

BOTANICAL DESCRIPTION

Common Name: American Cranberry
Scientific Name: *Vaccinium macrocarpon* Aiton
Botanical Family: Ericaceae (éricacées, heaths)
Physical Description: A small, trailing evergreen shrub that reaches 1–4 in. (2.5–10 cm) in height. The simple, alternate leaves are small (0.25–0.75 in./0.6–1.9 cm). The young leaves are light green to maroon, whereas the mature leaves are deep green. Clusters of light pink flowers appear in early to mid-summer, and later small, bright red berries develop.

Common Name: European Cranberry, Guelder Rose, Crampbark, Cranberry Tree
Scientific Name: *Viburnum opulus* L.
Botanical Family: Caprifoliaceae (honeysuckle)
Physical Description: This tall, thick, deciduous shrub reaches up to 4 m (~13 ft) in height. The branches are smooth (glabrous) with maple-like leaves. Clusters of beautiful, white flowers produce small bright red berries.

EXPOSURE

Traditional

Cranberry juice is a common, traditional preventative, a treatment for the symptoms of urinary tract infection, and a deodorant for the odors associated with urinary incontinence.[1–3]

Current

Although there is limited evidence that the daily use of cranberry juice reduces the incidence of urinary tract infections, there are few data supporting the use of cranberry products to treat active urinary tract infections or to prevent the recurrence of urinary tract infections in patients with indwelling catheters or neurogenic bladders. In two acceptable, randomized, controlled clinical trials, cranberry products significantly reduced (RR = 0.61, 95% CI: 0.40–0.91) the incidence of urinary tract infections in women over a 12-month period compared with placebo control.[4] The dose of cranberry products in the two trials were 7.5 g cranberry in 50 mL cranberry-lingonberry juice in one trial[5] and 750 mL cranberry juice daily (or cranberry capsules twice daily) in the other trial.[6] There was no significant difference in the incidence of urinary tract infections between cranberry juice and cranberry capsule groups. The ingestion of cranberry juice may reduce the risk of urinary stone formation by increasing urinary citrate,[7] but there are inadequate clinical data supporting the use of cranberry juice to decrease the risk of calcium oxalate, urate, or brushite renal stones.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Regulatory

In the United States, cranberries and cranberry juice are a food and dietary supplement.

PRINCIPAL INGREDIENTS

Chemical Composition

Cranberries contain about 90% water along with flavonoids, anthocyanins, triterpenoids, catechin, phenolic compounds, glucose, fructose, and vitamin C. The carbohydrate load of cranberries is relatively large, particularly for diabetic patients. Cranberries contain large amounts of benzoic and phenolic acids (i.e., ~5–6 g/kg fresh weight) with the most abundant acids being benzoic acid (4.7 g/kg fresh weight), *p*-coumaric acid (0.25 g/kg fresh weight), and sinapic acid (0.2 g/kg fresh weight).[8] The benzoic and phenolic acids occur primarily in the bound forms, primarily to sugars with only about 10% of these compounds occurring as free acids. The major phenolic compound in freshly squeezed cranberry juice is benzoic acid, whereas quercetin and myricetin are the major flavonoids.[9]

Physiochemical Properties

The high citric and quinic acid content of cranberries imparts the characteristic tart taste. Blueberries are a more palatable source of proanthocyanidin compounds than cranberries. Although the presence of quinic acid in cranberries causes the urinary excretion of large amounts of hippuric acid,[10] this effect is relatively transient and probably does not produce significant antibacterial effect.[11] The ingestion of 360 mL cranberry juice daily can lower urinary pH, but the pH does not usually decrease below pH 5.5.[12]

The ingestion of cranberry juice produces mixed effects on the propensity to form urinary stones. In a study of 12 normal subjects and 12 calcium oxalate stone formers, the daily ingestion of 1 L cranberry juice reduced urinary pH (5.97 to 5.67), decreased urinary uric acid excretion, and increased calcium oxalate (i.e., ~18%) and undissociated uric acid in the urine.[13] Overall, this study suggested that the daily use of cranberry juice potentially increases the risk of calcium oxalate and uric acid stones, whereas the risk of brushite stones was potentially decreased. However, the clinical effect of these changes is probably small.

Mechanism of Action

The ingestion of cranberries results in the inhibition of bacterial adherence to mucosal surfaces. Most pathogenic *E. coli* express P fimbriae, which mediate the adherence of the bacteria to uroepithelial cells. Proanthocyanidin compounds in cranberries inhibit the ability of P-fimbriated *E. coli* to attach to isolated uroepithelial cells at concentrations of 10–50 μg/mL.[14] The inhibition of the papG fimbrial attachment of uropathogenic strains of *E. coli* to human cells resides in the A-type proanthocyanidin compounds rather than a B-type dimer or the (−)-epicatechin monomer.[15] The purified active fraction of the A-type proanthocyanidins contains over 200 compounds including 1-*O*-methylgalactose, prunin, and phlorizin.[16] Fructose also inhibits the adherence of type 1 (mannose-specific) fimbriated *E. coli*. However, the direct bacteriocidal activity of cranberry juice appears weak.[17]

DOSE RESPONSE

Treatment regimens for cranberry products include 480 mL cranberry juice daily for urine odors[1] and 300 mL cranberry juice cocktail (25–33% juice with sweetener) for the treatment of bacteriuria and pyuria.[18] The large number of withdrawals from clinical trials for the use of cranberry products to prevent urinary tract infections suggest that adverse effects occur with doses in the range of 750-mL cranberry juice over 12 months, but there are few data on the actual side effects. The daily ingestion of 300 mL cranberry juice was well tolerated by 376 older patients (>60 years old) in a randomized, placebo-controlled, double-blind clinical trial evaluating the use of cranberry juice for the reduction of the time to onset of first urinary tract infection.[19] The ingestion of large amounts (>3–4 L) of cranberry juice daily can produce gastrointestinal distress manifest by diarrhea and nausea.

TOXICOKINETICS

There are limited data on the toxicokinetics of the ingredients in cranberry products, in part because the active ingredients have not been identified. Flavonoids inhibit cytochrome P450 enzymes including CYP2C9; therefore, potential interactions occur between the use of cranberries and warfarin.[20] A case report associated a persistently elevated international normalized ratio (INR) with the use of cranberry juice in a patient on warfarin therapy for a prosthetic mitral valve.[21] The elevation in the INR was detected 2 weeks after the patient began drinking cranberry juice.

CLINICAL RESPONSE

The ingestion of large amounts of cranberry products may potentially cause gastrointestinal distress including

nausea, vomiting, and diarrhea. There are no reports of serious toxic reactions associated with the use of cranberries except the development of dehydration and metabolic acidosis associated with the ingestion of large amounts of cranberry tea.[22]

DIAGNOSTIC TESTING

Methods for analysis of phenolic compounds in cranberries include gas-liquid chromatography, high performance liquid chromatography (HPLC), capillary electrophoresis (CE), and capillary gas chromatography/mass spectrometry (GC/MS). In contrast to gas-liquid chromatography, HPLC and CE do not require derivatization prior to quantitation, but these latter methods do not provide sufficient separating performance or identifying power. Consequently, capillary GC/MS remains the method of choice for determination of phenolic compounds in fruit juices, such as cranberry juice.

TREATMENT

Treatment is supportive. Serious adverse effects usually are not associated with the ingestion of cranberry products. Decontamination measures are not necessary.

Chapter 64

DONG QUAI
[*Angelica sinensis* (Oliv.) Diels]

HISTORY

Dong quai is one of the most popular Chinese herbs with thousands of years of use in traditional Chinese medicine, primarily for gynecological complaints (e.g., "female ginseng"). In the 6th century AD, Lei Gong's *Treatise on Preparation of Materia Medica* described the herbal use of dong quai as a tonic for promoting the circulation, regulating the menstrual cycle, strengthening the heart, and lubricating the bowel.[1] In Europe during the late 1800s, an extract of dong quai (eumenol) was a popular herbal remedy for menstrual cramps and bleeding. There is a recent resurgence of interest in dong quai for the treatment of gynecological complaints based on proposed weak estrogen-like properties, but there are few clinical data to support the efficacy of dong quai for gynecological diseases.

BOTANICAL DESCRIPTION

Other similar plants used for the treatment of gynecological complaints include *Angelica acutiloba* (Siebold & Zucc.) Kitag. (dong dang gui, tang-kuei), *Angelica gigas* Nakai (Korean angelica), *Angelica dahurica* (Hoffm.) Franch. & Sav. (Bai zhi), and *Angelica pubescens* Maxim. (Du huo). However, *A. sinensis* remains the most popular type of *Angelica* in herbal therapy.

Common Name: Dong Quai (Chinese Angelica, Dang Gui, Tang Kuei, Tan Kue, Tanggwi, Toki)
Scientific Name: *Angelica sinensis* (Oliv.) Diels
Botanical Family: Apiaceae (Umbelliferae)

Physical Description: This fragrant, perennial herb grows to about 6 ft (~2 m) with purple, smooth stems, which contain linear striations. In June and July, white flowers appear in umbrella-like clusters.

Distribution and Ecology Dong quai (*Angelica sinensis*) is a fragrant, perennial herb, which grows in rich, well-drained soil on cold, damp mountain slopes in mainland China, Korea, and Japan. Commercial cultivation of *Angelica sinensis* occurs in the Gansu, Sichuan, Yunnan, Shaanxi, and Hubei provinces of China.

EXPOSURE

Sources

After 3 years of cultivation, the roots of *A. sinensis* are harvested and stored in sealed containers under cool, dry conditions to prevent mildew and evaporation of the volatile oils.

Medicinal Uses

Traditional

The herb, *Angelica sinensis*, is a traditional restorative tonic, blood purifier, and a treatment for premenstrual syndrome, menopause, and dysmenorrhea. Typically, dong quai is combined with other herbs (e.g., chamomile) for the treatment of these conditions.[2] The root is the most common portion of the plant used in Chinese medicine. The 10–25 cm (~4–10 in.), grayish-brown to

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

dark brown root is divided into three parts (head, body, tail) with different medicinal properties ascribed to each part. Other traditional uses include the treatment of hypertension and other cardiovascular conditions (thromboangiitis, cor pulmonale, Berger's disease, Raynaud's disease), headache, neuralgias, chronic rhinitis, anxiety, insomnia, forgetfulness, chronic constipation, inflammation, and infectious diseases (herpes zoster, hepatitis, chronic glomerulonephritis).[3,4] The water soluble sodium salt of ferulic acid (sodium ferulate) is used in China as an antithrombolytic agent and as a treatment for cardiovascular and cerebrovascular diseases.[5] Native Americans used this herb for the treatment of headaches, renal dysfunction, cirrhosis, and bladder problems.

Current

In the United States and Europe, dong quai is primarily used as a flavoring agent for a variety of commercial products including ice cream, candy, cream fillings, liqueurs, and vermouth. There is little clinical evidence to support the use of dong quai for the treatment of vasomotor symptoms associated with menopause.[6,7] A double-blind, placebo-controlled study of 71 postmenopausal women did not detect a significant difference between the dong quai groups (4.5 g dong quai root daily standardized to 0.5 mg ferulic acid/kg) and placebo.[8] The endpoints were the Kupperman Index scores, number of hot flashes, vaginal maturation index, and endometrial thickness.

Regulatory Status

In the United States, dong quai is a dietary supplement. The German Commission E does not list dong quai as an approved herbal medication.

PRINCIPAL INGREDIENTS

Chemical Composition

Potentially bioactive components of dong quai include ferulic acid ($C_{10}H_{10}O_4$), ligustilide ($C_{12}H_{14}O_2$), and other alkylphthalide compounds (e.g., 6,7-dihydroxyligustilide, senkyunolide A).[9] The content of ferulic acid in extracts of dong quai depends on the extraction method as well as variations between individual plants with ranges of approximately 0.2–1.4 mg/g.[10] The ferulic acid concentration in an aqueous ethanol extract of two samples of raw root of dong quai was 0.31 mg/g and 0.48 mg/g as measured by capillary zone electrophoresis.[11] In 10 samples from the root of dong quai, the ferulic acid content ranged from about 0.17 mg/g to approximately 0.53 mg/g.[10] In addition to ligustilide and ferulic acid, the major components of the dried root of dong quai are *n*-butylidenephthalide, *n*-butylphthalide, vanillin, linoleic acid, nicotinic acid, and succinic acid.[1,12] The root of dong quai also contains the ester of ferulic acid (coniferyl ferulate). Figure 64.1 and Figure 64.2 display the chemical structures of ferulic acid and ligustilide, respectively. The essential oil represents about 0.4–0.7% of the root using standard Chinese aqueous-extracting methods, and this essential oil contains about 100 constituents.[1] Based on subwindow factor analysis and spectral correlative chromatography of an essential oil from the main root of dong quai, the major ingredient was ligustilide, which accounted for about 19% of the total.[13] Minor constituents of the essential oil included α-pinene, butylidenephthalide, carvacrol, alloocimene, 4-vinylguaiacol, and *d*-limonene. The aromatic properties of the volatile oil from dong quai result primarily from ligustilide compounds. In samples of three whole roots of dong quai (*Angelica sinensis*), the total content of ligustilide compounds ranged from about 10–16 mg/g dry weight as measured by liquid chromatography/mass spectrometry.[14] Potentially toxic compounds in dong quai include photosensitizing psoralens and the carcinogen, safrole. There are conflicting data on the amount of natural coumarin compounds (angelol I, angelol H, scopoletin, angelicone, bergapten, 7-desmethylsuberosin, oxypeucedanin, osthole, psoralen) present in dong quai with the amounts of these

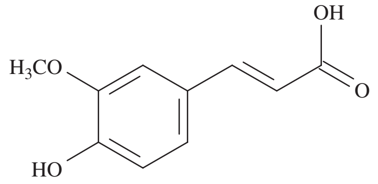

FIGURE 64.1. Chemical structure of ferulic acid (CAS RN: 1135-24-6).

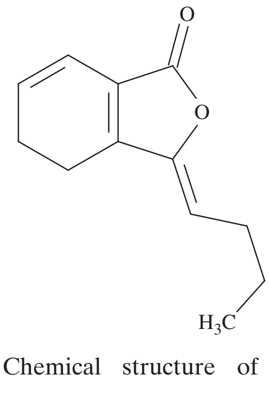

FIGURE 64.2. Chemical structure of ligustilide (CAS RN:4431-01-0).

compounds in *Angelica sinensis* being relatively low compared with other related species, such as *A. dahurica*.[15,16]

Physiochemical Properties

In vitro studies indicate that dong quai has only weak estrogen receptor binding properties and little upregulation of progesterone receptor mRNA.[17] Table 64.1 lists some physiochemical properties of ferulic acid. This compound is a poorly water soluble, weak organic acid; therefore, ferulic acid is not a major component of aqueous extracts of dong quai.

DOSE RESPONSE

There is little standardization of the traditional dose of dong quai. Some commercial products use approximately 1% ligustilide or 0.5 ppm ferulic acid as their standard concentration for dong quai. Common traditional doses of dong quai in Chinese medicine range from about 1–5 g powdered or dried root 3 times daily.[16] Decoctions of dong quai typically involve the boiling or simmering of 1–3 teaspoons of the root in 1 cup of water for 2–5 minutes followed by 5–10 minutes of brewing. The daily dose of the decoction is about one to three cups. One gram of 100% aqueous extract of dong quai is equivalent to approximately 4 grams of the raw root.[1]

TOXICOKINETICS

There are few data on the pharmacokinetics of ferulic acid and ligustilide. Most herbal publications do not recommend the use of dong quai in patients on anticoagulants because of the presence of natural coumarin compounds in this herb and potential antiplatelet effects. A single case report temporally associated the use of dong quai with mild elevation of baseline prothrombin times in a patient on warfarin.[18] However, there are limited experimental data to confirm the clinical significance of any potential effect of dong quai on coagulation parameters in patients on anticoagulants. *In vitro* animal studies using washed platelets also suggest that some components (osthole, ferulic acid) of dong quai inhibit platelet aggregation by several mechanisms including inhibition of thromboxane A_2 formation and arachidonic acid metabolism.[19] Although the ingestion of dong quai could potentially enhance the effects of antiplatelet drugs, these activities are relatively weak, and there are insufficient data to conclude that such effects are clinically relevant.

TABLE 64.1. Some Physiochemical Properties of Ferulic Acid

Physical Property	Value
pKa Dissociation Constant	4.58 (25 °C/77 °F)
log P (Octanol-Water)	1.51
Water Solubility	5970 mg/L (25 °C/77 °F)
Vapor Pressure	2.69E-06 mmHg (25 °C/77 °F)
Henry's Law Constant	7.96E-14 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	4.83E-11 cm^3/molecule-second (25 °C/77 °F)

CLINICAL RESPONSE

There are few reports of toxicity associated with the use of dong quai. A case report temporally associated the daily use of dong quai pills for one month by a 35-year-old man with the development of gynecomastia that resolved after the cessation of the use of dong quai.[20] All laboratory tests were normal including plasma follicle stimulating hormone, luteinizing hormone, estradiol, testosterone, and prolactin concentrations.

DIAGNOSTIC TESTING

The root of dong quai contains at least 100 constituents, and separation of these components is a complex process that may require multidimensional separation techniques, such as two-dimensional liquid chromatography/mass spectrometry[12] and subwindow factor analysis/spectral correlative chromatography.[13] Methods for the detection of ferulic acid include high performance liquid chromatography and capillary zone electrophoresis.[11] Extracts of dong quai contain phenolic compounds (e.g., coniferyl ferulate), which can hydrolyze during the extraction process to form ferulic acid. In a study of 10 samples from the root of dong quai using methanol-formic acid extraction, the ratio of total measured ferulic acid to free (nonhydrolyzed) ferulic acid ranged from 1.53–9.73.[10]

TREATMENT

Treatment is supportive.

Chapter 65

FEVERFEW
(*Tanacetum parthenium* Schultz Bip.)

HISTORY

Feverfew is an ancient remedy for fever, pain, and menstrual problems that has been used since ancient Greek times. The 17th century herbalist Culpepper recommended the use of this herb for miscarriages, colic, and opium addiction.[1] Additionally, John Gerard's *Herball* recommended the use of feverfew for the treatment of inflammation and swelling including St. Anthony's Fire. Feverfew was considered the "medieval aspirin."

BOTANICAL DESCRIPTION

Common Name: Feverfew, Featherfew, Wild Chamomile, Wild Quinine, Bachelor's Button, Santa Maria

Scientific Name: *Tanacetum parthenium* (L.) Schultz Bip. [*Matricaria parthenium* (L.), *Leucanthemum parthenium* (L.) Gren. and Gordon, *Pyrethrum parthenium* (L.), *Chrysanthemum parthenium* (L.) Bernh.]

Botanical Family: Asteraceae (sunflowers, tournesols, Compositae)

Physical Description: This hardy, aromatic annual plant has bright green, chrysanthemum-like leaves. The height of feverfew reaches up to 2 ft (~60 cm). The deeply cut leaves have a sharp, unpleasantly bitter taste. Thick, daisy-like flowers with yellow centers appear from summer until mid-fall.

Distribution and Ecology: Feverfew is a native herb of Asia Minor that ranges from southeastern Europe to Asia. This plant is naturalized in well-drained soil in mountain scrub, rocky slopes, and disturbed areas of the United States and the United Kingdom.

EXPOSURE

Sources

Use of feverfew typically involves the use of fresh leaves or the ingestion of capsules or tablets composed of dried leaves. In a study of commercial Canadian and European herbal preparations of dried feverfew leaves, the parthenolide content ranged from 0 to >1%.[2] A study of 13 commercial feverfew capsules, tablets, and powders demonstrated parthenolide content ranging from 0–0.36%.[3] Only three of these products displayed accurate parthenolide concentrations on their labels. In a study of 21 commercial US capsules containing 25–500 mg dried feverfew leaves, the parthenolide content ranged from 0.14–0.74%.[4] Consequently, the daily dose of these products could vary by as much as 160-fold.

Medicinal Uses

Traditional

Traditional uses for feverfew include the treatment of migraine headache, fever, dysmenorrhea, psoriasis, and arthritis. Other uses include asthma, toothaches, insect bites, stomach cramps, and threatened abortions.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Current

Feverfew is a common herb administered as dried leaf capsules for prophylaxis of chronic migraine headaches, but there is limited evidence supporting efficacy.[5] In particular, there is insufficient evidence from randomized, double-blind clinical trials to conclude that the use of feverfew prevents migraine headaches or that the use of feverfew is more efficacious than other current prophylactic treatments (propanolol, topiramate). Several small, blinded, placebo-controlled studies suggest that the prophylactic use of dried feverfew capsules (i.e., approximately 50–80 mg daily) moderately reduces the frequency and severity of symptoms (nausea, vomiting, pain) of migraine headache, as measured by self-reported symptoms.[6,7] A randomized, double-blind, placebo-controlled, multicenter, parallel-group study followed 170 individuals who suffered from migraine headaches. They were treated with a CO_2 extract of feverfew (6.25 mg 3 times daily) for 16 weeks after a 4-week baseline period.[8] The primary effect was a reduction in the total number of migraine days and migraine duration rather than the intensity of the headache. When compared with baseline, a statistically significant reduction was barely achieved ($P = 0.0456$) in the frequency of migraine attacks (1.9 vs. 1.3, respectively). There was no significant increase in adverse effects during the treatment period. A double-blind, placebo-controlled multicenter randomized clinical trial compared three dosage regimens of CO_2 feverfew extract (2.08 mg, 6.25 mg, 18.75 mg) daily for 12 weeks with placebo.[9] When compared with the 4-week baseline, there was no statistically significant difference between the groups with respect to the total number of migraine attacks during the last 28 days of treatment. Additionally, there was no significant dose response relationship. There is also no clear scientific evidence that the use of feverfew reduces symptoms of rheumatoid arthritis.[10]

Regulatory Status

Suggested standardization of feverfew preparations primarily involves the establishment of minimum parthenolide concentrations in the range of 0.1–0.2%. Currently, there is substantial variation in the concentration of parthenolide in various commercial preparations of feverfew-based high performance liquid chromatography (HPLC) and gas chromatography (GC) analyses.[11]

PRINCIPAL INGREDIENTS

Chemical Composition

Feverfew leaves contain substantial amounts of sesquiterpene lactones, principally the germacranolide, parthenolide, which occurs in concentrations in dried leaves of up to 1% by dry weight.[12] Figure 65.1 displays the sesquiterpene structure of parthenolide (CAS RN: 29552-41-8, CAS RN: 20554-84-1). The concentration of parthenolide in feverfew preparations varies depending on the source and a variety of genetic and environmental factors including strain, sunlight, water stress, location, season (preflowering vs. postflowering), and harvesting techniques.[13,14] The highest concentrations of parthenolide occur in the flowering tops and leaves, whereas the stalks and roots contain very small amounts of parthenolide. Analysis of plant parts from a UK specimen of feverfew revealed the following parthenolide concentrations: flowering tops, 1.38%; leaves, 0.95%; stalks, 0.08%, and roots, 0.01%.[2] Feverfew varieties with a light green-yellow colored variety have significantly higher mean parthenolide concentrations (1.61% ± 0.61%, dry weight) than darker-leafed varieties (<0.5%).[15] Other less common terpenoid compounds in feverfew include germacrene D, β-farnesene, chrysanthemonin, chrysanthemolide, magnoliolide, santamarine, and reynosin. The most common monoterpene compound in feverfew is camphor. Rare compounds in feverfew include the guaianolides, 8α-hydroxyestafiatin, endoperoxide tanaparthin-α-peroxide, canin, 10-epi-canin, and seco-tanapartholide A and B.[16] Lipophilic flavonols in the leaves and flowers of feverfew include tanetin (6-hydroxykaempferol 3,7,4′-trimethyl ether), 6-hydroxykaempferol 3,7-dimethyl ether, quercetagetin 3,7-dimethyl ether and quercetagetin 3,7,3′-trimethyl ether.[17] The essential oil of feverfew contains primarily camphor and *trans*-chrysanthenyl acetate along with smaller amounts of a variety of monoterpenes (camphene, α- and β-pinene, sabinene, myrcene, *p*-cymene, α- and γ-terpinene, terpinolene, terpine-4-ol, α-terpineol), oxidized monoterpenes (linalool, linalyl acetate, bornylacetate), sesquiterpene lactones (β-caryophyllene, *trans*-β-farnesene, germacrene), and eugenol.[18]

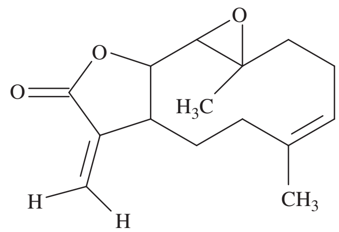

FIGURE 65.1. Chemical structure of parthenolide.

Physiochemical Properties

In vitro studies suggest that feverfew extracts inhibit platelet aggregation and the release of serotonin from

platelets.[19] Thromboxane synthesis was unaffected by feverfew. Monoterpenes are the primary compounds released by aerial parts of feverfew including α-pinene, camphene, limonene, γ-terpinene, (*E*)-β-ocimene, linalool, *p*-cymene, (*E*)-chrysanthenol, camphor, and (*E*)-chrysanthenyl acetate.[20] The air around these plants did not contain detectable amounts of parthenolide or other sesquiterpene lactones as measured by dynamic headspace techniques along with GC and gas chromatography/mass spectrometry (GC/MS).

Mechanism of Toxicity

The identity of the active constituent in feverfew is unclear. A suggested mechanism of action is an anti-inflammatory effect from the major ingredient (parthenolide) in feverfew as a result of the attenuation of inflammatory processes including the degradation of the inhibitory protein-κBα, the activation of significant nuclear factor κB, and the expression of inducible nitric oxide synthase.[21] *In vitro* studies suggest that parthenolide blocks the activation of key central areas (i.e., nucleus trigeminalis caudalis) in the pathogenesis of migraine.[22]

DOSE RESPONSE

In England and Canada, standardization of feverfew products requires the presence of least 0.2% parthenolide. Traditional daily oral doses of feverfew include two to three dried leaves (approximately 60 mg) or 50–250 mg of dried leaf, standardized to 0.2% parthenolide.

TOXICOKINETICS

Kinetics

There are inadequate pharmacokinetic data to determine the bioavailability of parthenolide. In a phase I dose escalation trial of feverfew, parthenolide was not detectable in plasma following the administration of oral daily doses up to 4 mg feverfew capsules (Tanacet™, Ashbury Biologicals, Inc., Toronto, Ontario, Canada), as measured by solid phase extraction and MS.[23] The limit of detection was 0.5 ng/mL. The plasma concentration of parthenolide in mice 1 hour after the gavage of 4 mg/kg (i.e., about 10 times the dose administered to the patients) was 27.8 ng/mL. *In vitro* studies suggest that sesquiterpene lactones, such as parthenolide are about 30–50% bound in the blood.[24] Epoxidation and/or allylic oxidation with or without allylic rearrangement of parthenolide form a variety of metabolites in feverfew including β-hydroxyparthenolide, costunolide, β-hydroxycostunolide, artemorin, and 3β-hydroxyanhydroverlotorin.[12]

Drug Interactions

Based on laboratory research on the inhibition of platelet aggregation, feverfew theoretically can increase the risk of bleeding following the ingestion of other drugs affecting hemostasis (e.g., aspirin, warfarin). However, there are few clinical data to suggest that this potential effect is clinically significant.

CLINICAL RESPONSE

The adverse effects associated with the administration of feverfew during clinical trials are typically mild and transient. The most common adverse effect following the use of herbal preparations of feverfew leaves are oral ulceration and inflammation.[25] Feverfew is one of the major weed pollens along with ragweed (*Ambrosia* spp.), sunflower (*Helianthus* spp.), and mugwort (*Artemisia* spp.).[26] There is substantial cross-reactivity between members of the Asteraceae family. In a study of 190 Asteraceae-allergic patients determined by positive skin tests to an Asteraceae mix, feverfew elicited the most (81%) positive responses followed by tansy (77%), chamomile (64%), and yarrow (41%).[27] Most atopic patients are also hypersensitive to allergens other than members of the Asteraceae family, such as nickel.[28] The major allergen (Par h 1) in feverfew contains significant sequence identity with sunflower allergens and the major allergen (Art v 1) of mugwort.[29] The rash associated with allergic reactions to feverfew is a diffuse, erythematous, and occasionally lichenified lesion with a photodermatitis-like distribution.[30] However, this rash involves the upper eyelids, submental area, and retroauricular regions of the face in contrast to true photodermatitis. Sensitization to the sesquiterpene lactones of feverfew does not necessarily imply sensitization to the associated volatile monoterpene compounds in feverfew.[31] Patients with hypersensitivity to members of the Asteraceae family [e.g., aster (*Aster* spp.), chrysanthemums (*Chrysanthemum X morifolium* Ramat.), marguerite (*Leucanthemum vulgare* Lam.), marigold (*Calendula* ssp., *Tagetes* spp.) ragweed (*Ambrosia* spp.), sunflower (*Helianthus annuus* L.), tansy (*Tanacetum vulgare* L.), yarrow (*Achillea millefolium* L.)] may develop cross-sensitivity to feverfew, primarily as a result of the presence of sesquiterpene lactones.[32,33]

Case reports suggest that the abrupt cessation of feverfew use for migraine prophylaxis causes the exacerbation of migraine symptoms.[7] Other symptoms associated with withdrawal include muscle stiffness, insomnia, arthralgias, and anxiety.

DIAGNOSTIC TESTING

Parthenolide is the principal sesquiterpene lactone in feverfew, and standardization of feverfew preparations typically involves the analysis of parthenolide content. Minimum content of parthenolide is usually 0.1–0.2%. Methods to determine parthenolide content include liquid chromatography,[3] HPLC with UV detection at 210 nm,[34] GC with flame ionization,[11] and nuclear magnetic resonance.[2] Some deterioration of parthenolide occurs during storage. Following storage of three samples of feverfew at room temperature in a lighted room for 9 months, the parthenolide content decreased by 50–65%.

TREATMENT

Treatment is supportive. Allergic dermatitis is treated with topical steroids and antihistamines.

Chapter 66

GARLIC

(*Allium sativum* L.)

HISTORY

The use of garlic dates back at least 5,000 years to the Babylonians.[1] Many ancient civilizations used garlic including the Egyptians, Phoenicians, Greeks, Romans, Chinese, Hindus, and Vikings. Reportedly, the construction workers on the Egyptian pyramids ate garlic to protect themselves from diseases, and grave diggers drank wine containing crushed garlic to protect themselves from the plague during the Middle Ages.[2] When the Russians depleted their supplies of penicillin during World War II, they used garlic poultices to treat wounds.

BOTANICAL DESCRIPTION

The name garlic is derived from the Anglo-Saxon words *gar* (spear) and *lac* (plant) that refer to the shape of garlic leaves. The genus *Allium* contains about 450 species including a variety of chives, onions, and leeks.

Common Name: Cultivated garlic

Scientific Name: *Allium sativum* L.

Botanical Family: Liliaceae (lily)

Physical Description: This perennial herb has a bulb consisting of a cluster of smaller bulbs (bulblets or cloves). The leaves are long, linear, and sword-shaped. The flowers are small, flat umbels.

Distribution and Ecology: *Allium* species are widely distributed over temperate regions of the northern hemisphere. The cultivated garlic probably originated in Central Asia.

EXPOSURE

Sources

Commercial available forms of garlic include raw garlic homogenate, garlic oil, garlic oil macerate, dehydrated garlic powder, and aged garlic extract. Figure 66.1 lists the major ingredients in these garlic preparations. Raw garlic homogenate is the most common form of garlic, and this preparation is equivalent to the aqueous extract of garlic with the principal ingredients being allicin (diallyl thiosulfinate), allyl methyl thiosulfonate, 1-propenyl allyl thiosulfonate, γ-glutamyl-S-alkyl-L-cysteine.[3] The concentration of sulfur-containing compounds (e.g., S-allyl cysteine) varies with preparation processes. Garlic essential oil is a steam distillation product of garlic that contains primarily sulfides (diallyl trisulfide, diallyl disulfide, allyl methyl trisulfide, allyl methyl disulfide, diallyl tetrasulfide) and no allicin or water-soluble fraction. Garlic powder is a flavoring agent for condiments and processed foods that contains alliin (up to 1%) and small amounts of oil-soluble sulfur compounds. Oil macerates are encapsulated mixtures of whole garlic cloves ground in vegetable oil. These preparations contain decomposed products of allicin (ajoene, dithiins, sulfides, residual alliin). Typically, the storage of sliced raw garlic in 15–20% ethanol for 20 months produces aged garlic extract that is relatively low in allicin and high in S-allyl cysteine and S-allylmercaptocysteine. Consequently, the hydroalcoholic extract of aged garlic contains primarily water-soluble constituents (S-allyl cysteine, S-allylmercaptocysteine) and small amounts of oil-soluble sulfur compounds.

Medicinal Uses

Traditional

Traditional uses of garlic include the treatment of parasites, skin diseases, wounds, gastrointestinal illnesses, flatulence, respiratory infections, intestinal parasites, leprosy, fever, and aging.

Current

The use of dried garlic powder causes some modest, short-term reduction (8–12 weeks) in total cholesterol concentrations, but these effects are not sustained over 6 months.[4] The consumption of garlic powder probably does not significantly lower plasma lipid concentrations when administered in conjunction with a low-fat, low-cholesterol diet.[5] Epidemiologic studies suggest some decreased risk of stomach and colon cancer following the high consumption of garlic and other allium vegetables (chives, leeks, onions, shallots),[6] but these studies are not well controlled for confounding variables. Although garlic has some modest antiplatelet aggregation activity *in vitro*,[7] there is no clear clinical evidence that the use of garlic reduces the risk of thrombosis. There is no reliable evidence that the use of garlic reduces blood pressure in hypertensive patients or serum glucose in diabetics. Additionally, there are insufficient data to support the use of garlic as an anti-infective agent.

Regulatory Status

Garlic products are marketed in the European Union (EU) as foodstuffs and as herbal medicinal products. The latter preparations are not available in all member nations. In the United States, garlic is generally recognized as safe (GRAS) as a dietary supplement and food additive. Garlic is also on the German Commission E list of approved herbs.

PRINCIPAL INGREDIENTS

Chemical Composition

The major flavoring constituents of garlic are sulfur compounds (diallyl disulfide, allyl sulfide, diallyl trisulfide), but preparation processes dramatically alter the type and concentrations of these compounds in garlic preparations.[8] These processes include steam distillation, simultaneous distillation and solvent extraction, solid-phase trapping solvent extraction, and headspace solid-phase microextraction. The primary sulfur-containing compounds in intact, whole garlic are γ-glutamyl-S-alk(en)yl-L-cysteines and S-alk(en)yl-L-cysteine sulfoxides (e.g., alliin, methiin). The odorless amino acid, alliin (S-allyl cysteine sulfoxide), accumulates during storage at cool temperatures, and garlic bulbs typically contain up to 1.8% alliin and 0.9% γ-glutamyl cysteine compounds along with small amounts of S-allyl cysteine.[9] Processing (i.e., crushing, cutting) whole, fresh garlic causes the release of the vacuolar enzyme, alliinase, which rapidly lyses cytosolic cysteine sulfoxides (e.g., alliin) into numerous alkyl alkane-thiosulfinate compounds including allicin (diallyl thiosulfinate, CAS RN:539-86-6). Allicin is usually absent from intact, fresh garlic bulbs. Figure 66.2 displays the chemical structure allicin. This odorous compound decomposes rapidly into various sulfides (e.g., ajoene, dithiins, diallyl sulfides), which contribute to the characteristic taste and flavor of garlic. Although freshly crushed garlic can contain small amounts of allicin, commercial products do not usually contain allicin, and allicin is not detectable in the blood after the ingestion of raw garlic or pure allicin.[9]

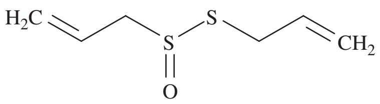

FIGURE 66.2. Chemical structure of allicin.

Additional constituents of garlic include steroidal glycosides, prostaglandins, lectins, fructan, essential oil, adenosine vitamins, essential amino acids, fatty acids, nicotinic acid, biotin, glycolipids, phospholipids, flavonoids, phenolics, and anthocyanins.[10] Garlic contains the allergen, alliin lyase, which cross-reacts with alliin lyases from other *Allium* species (e.g., leek, shallot, onion),[11] as well as the photocontact allergen, diallyl disulfide.[12] The main constituents of garlic oil are the hydrophobic compounds, allylpolysulfides (diallyl sulfide, diallyl disulfide, diallyl trisulfide). Flavonoids are polyphenols with diphenylpropane ($C_6C_3C_6$) skeletons. The four major classes of flavonoids are 4-oxo-flavonoids (flavones, flavonols), isoflavones, flavan-3-ol derivatives (catechin, tannins), and anthocyanins. *Allium* vegetables (onions, leek, chives, garlic) contain relatively high concentration of flavonoids. In a study of aqueous methanol extracts of edible plants, the total flavonoid content of garlic was 957 mg/kg dry weight consisting primarily of the flavonols, myricetin (639 mg/kg) and quercetin (47 mg/kg) along with the flavone, apigenin (217 mg/kg).[13]

Physiochemical Properties

The characteristic odor of garlic results from sulfur-containing compounds.[1] Aging of garlic reduces the

content of sulfur compounds (e.g., alliin) and decreases the odor associated with garlic. The water-soluble precursor of the compound, alliin, is far more stable than its decomposition product, allicin. Both alliin (S-allyl cysteine sulfoxide) and alliinase are stable in dry environments. Allicin is a highly reactive, odorous liquid that decomposes rapidly into secondary products at temperatures above 60 °C (140 °F). At room temperature, the half-life of allicin is about $2^1/_2$ days in crushed garlic.[14] Consequently, heat-treated garlic contains mainly alliin. *In vitro* studies indicate that allicin easily diffuses across phospholipid membranes and into the cytoplasm of red blood cells.[15] Water soluble sulfur compounds (e.g., hydroalcoholic extracts) in garlic are probably less toxic than the oil-soluble organosulfur constituents of garlic.[16] S-allyl cysteine is an odorless, stable, water-soluble compound.

DOSE RESPONSE

Standard daily doses of garlic are as follows: raw garlic, 4 g; dried garlic powder tablet, 600–1200 mg (standardized to 1.3% alliin or 0.6% allicin); or aged garlic extract, 7.2 g.[17] The use of aged garlic extract in doses up to 10 g has not caused significant adverse effects in clinical trials.[9] In a clinical trial, the maximum tolerable dose of garlic extract was 25 mL.[18]

TOXICOKINETICS

Kinetics

The absorption of the water-soluble compound, S-allyl cysteine, is relatively rapid and complete.[19] The oil-soluble organosulfur compounds (allicin, diallyl sulfide, ajoene, vinyldithiins) generally are not detectable in blood, even after ingestion of large amounts of garlic. Garlic preparations contain allicin, which decomposes in the stomach and intestines to release allyl sulfides, disulfides, and other volatile compounds. The main sulfur-containing volatile metabolite in the breath after garlic consumption is allyl methyl sulfide with allyl methyl disulfide being a minor volatile metabolite.[20] These studies also indicate that *d*-limonene and *p*-cymene are detectable in the breath of volunteers after consuming garlic. S-allyl cysteine appears in the blood after ingestion of garlic as a result of the hydrolysis of γ-glutamyl-S-allyl-L-cysteine by γ-glutamine-trans-peptidase. *N*-acetylation of S-allyl-cysteine by *N*-acetyltransferase produces the urinary biomarker, S-allyl-mercapturic acid. Other metabolites detectable after ingestion include methylates of *N*-acetyl-S-(2-carboxypropyl) cysteine and *N*-acetyl-S-allyl cysteine.[21]

Drug Interactions

In vitro studies suggest that sulfide constituents in garlic can potentially induce the cytochrome P450 isoenzymes, CYP3A4, CYP2C9, and CYP2C19.[22] The *in vitro* activity of CYP2D6 is not usually affected by constituents in garlic.[23] The clinical relevance of these potential interactions remains unclear. Human studies suggest that regular use of garlic can reduce the bioavailability of HIV-1 protease inhibitors (saquinavir and, to a lesser extent, ritonavir). In a study of 10 healthy volunteers, the use of garlic caplets (twice daily for 20 days) resulted in a significant decline in the plasma concentration of saquinavir, an HIV-1 protease inhibitor.[24] Although the exact mechanism of this effect was unclear, the similarity in the reduction of the AUC, the mean maximum concentration, and the 8-hour concentration of saquinavir suggested that garlic affected the bioavailability of saquinavir, rather than its systemic clearance. A study of 14 healthy volunteers receiving 3.6 g garlic tablets (primarily alliin, alliinase) daily for 14 days did not detect significant differences in the pharmacokinetics of the probe substrates dextromethorphan (CYP2D6) or alprazolam (CYP3A4), when comparing baseline with garlic-treated phases.[25] A similar study of volunteers using garlic oil, which contains little alliin and alliinase, also did not demonstrate any significant effect of garlic oil on probe substrate, midazolam (CYP3A4),[26] but a similar study in elderly subjects detected a mean 22% decrease in CYP2E1 activity following the daily use of garlic oil for 28 days.[27]

The evidence for an interaction between garlic and coagulation remains conflicting. A case report suggested that the use of large amounts of garlic can cause platelet disorders and/or hemorrhage,[28] and another case report temporarily associated a reduction of the international normalized ratio (INR) below therapeutic range during the use of garlic tablets (600 mg/daily) in addition to the ingestion of fluindione.[29] Normalization of the INR followed the cessation of garlic use. However, a double-blind, placebo-controlled study of 14 healthy men did not detect a clinical significant effect of typical garlic consumption on platelet aggregation.[30]

CLINICAL RESPONSE

Adverse Reactions

The most frequent side effect of garlic use is breath and body odor. Consumption of excessive amounts of raw garlic, particularly on an empty stomach, can cause flatulence, nausea, and abdominal discomfort.

Acute Effects

Fresh garlic is a potential source of *Salmonella virchow*;[31] therefore, the consumption of garlic contaminated with *Salmonella* species can cause acute gastroenteritis and salmonellosis. Additionally, case reports document chopped garlic in soybean oil as a potential source of botulism.[32] Case reports describe exposure to garlic with a variety of skin reactions including irritant contact dermatitis,[33] superficial and deep, partial-thickness chemical burns,[34,35] local urticaria,[36] photocontact allergies,[37] immediate hypersensitivity reactions,[38] and delayed hypersensitivity. Most topical reactions to garlic result from irritation rather than an allergic reaction, particularly following exposure to fresh crushed garlic or garlic oil.[39] An eczematous skin lesion can develop after chronic exposure to garlic in sensitized individuals.[40,41] The intentional application of crushed, raw garlic to the skin can produce second-degree chemical burns, particularly when applied as a poultice.[42,43] The degree of skin injury depends on a variety of factors including duration of exposure, pre-existing skin conditions, anatomic area of skin, and freshness of the garlic.[44] The irritant compound is heat sensitive; therefore, cooked garlic does not cause skin burns. Occasional case reports associate occupational contact dermatitis with exposure to garlic, particularly in workers who cut garlic. These case reports have described a low-grade, hyperkeratotic fingertip dermatitis with fissures on the thumb, index, and middle finger of the nondominant hand.[45,46] Other allergic reactions associated with garlic exposure include acute bronchospasm in atopic individuals,[47] rhinoconjunctivitis,[48] and anaphylaxis.[49] Potential allergens in garlic include diallyl disulfide and alliin lyase.[50]

DIAGNOSTIC TESTING

Analytical Methods

High performance liquid chromatography (HPLC) with UV detection and gas chromatography/mass spectrometry (GC/MS) are common methods for the determination of sulfur compounds (e.g., allicin) in garlic. Methods for the simultaneous detection of alliin, deoxyalliin, allicin and dipeptide precursors in garlic products are available using HPLC with a diode-array UV detector and ion trap mass spectrometry (electrospray ionization).[51] Limits of detection for these methods are in the range of 0.1–0.5 nmol.

Biomarkers

The urinary metabolite, S-allyl-mercapturic acid, is a biomarker of garlic use that results from the hydrolysis and *N*-acetylation of γ-glutamyl-S-allyl-L-cysteine.[52] In a study of 5 healthy volunteers administered garlic tablets, the mean elimination half-life of S-allyl-mercapturic acid in urine was 6.0 ± 1.3 hour.[53] The limit of detection for S-allyl-mercapturic acid in urine samples was 10 μg/mL, as measured by GC with sulphur-selective detection. This biomarker is stable in frozen urine samples at –20 °C (–4 °F) for at least 3 months. S-allyl cysteine is stable for at least 12 months at ambient temperature.[54] S-allyl-mercapturic acid is not a unique biomarker of garlic use because of the presence of similar sulfur compounds in other *Allium* species (e.g., onion, leek, chives). β-Chlorogenin is the sapogenin of eruboside B, which is the characteristic saponin of crushed raw garlic. Except for elephant garlic (*A. ampeloprasum*), this saponin is not usually present in other *Allium* vegetables.[55]

TREATMENT

Treatment of adverse reactions associated with garlic is supportive including the use of standard treatment methods for contact dermatitis (topical steroids) or anaphylaxis (epinephrine, antihistamines).

Chapter 67

GERMANDER
(*Teucrium chamaedrys* L.)

HISTORY

Germander is an ancient herbal treatment for a variety of illnesses including stomach ailments, bronchitis, wounds, and diabetes mellitus. In 1992, the French Health Authority suspended the marketing of herbal preparations containing *Teucrium chamaedrys* after the publication of a report of 26 French cases of acute hepatitis associated with the consumption of herbal preparations containing wild germander.[1] Other countries in Europe and North America soon prohibited the use of herbal preparations containing *T. chamaedrys* L.

BOTANICAL DESCRIPTION

There are over 300 *Teucrium* species, which inhabit primarily the northern temperate and subtropical regions of the eastern hemisphere. Most *Teucrium* species are potentially hepatotoxic as a result of the presence of variable amounts of neoclerodane diterpenoid compounds including *T. canadense* L. (American or Canadian germander), *T. chamaedrys* L. (wild germander), *T. capitatum* L. (cat thyme), *T. polium* L. (golden germander), and *T. fruticans* L. (shrubby germander).[2,3] *Teucrium* species can taint herbal preparations of dog skullcap (*Scutellaria lateriflora* L.).[4] However, this contamination can be detected using digital photomicroscopy to identify abundant bristle-like trichomes (leaf of *T. canadense* L.) or a waxy cuticle with numerous glandular scales (leaf of *T. chamaedrys*).[5] *Scutellaria lateriflora* L. lacks both of these anatomical characteristics.

Common Name: Wild Germander, Wall Germander

Scientific Name: *Teucrium chamaedrys* L.

Botanical Family: Lamiaceae (Labiatae, Mint)

Physical Description: This somewhat hairy, evergreen shrub grows up to about 1 ft (~0.3 m) in height. The indented, opposite, dark green leaves are approximately 0.5 to 1.5 in. (~1.3–3.8 cm) long with a pattern similar to an oak leaf. The scented, rose-colored, labiate flowers appear from July to September in three to six flowered whorls on leafy, terminal spikes. The seeds ripen from August to September.

Distribution and Ecology: This plant prefers warm, dry areas on rocky soil or waste areas. The range of this plant is southern Europe and the Mediterranean with the plant naturalized in the United Kingdom and the United States.

Common Name: Golden Germander, Felty Germander

Scientific Name: *Teucrium polium* L.

Botanical Family: Lamiaceae (Labiatae, Mint)

Physical Description: This low-growing perennial plant grows up to about 1–1½ ft (~0.3–0.5 m) with erect, simple elongated ending in a paniculate or corymbose inflorescence. The sessile, oblong leaves are about 1 in. (2.5 cm) in length. The inconspicuous flowers are white to pale cream-colored and bloom from June to August.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Distribution and Ecology: This small shrub inhabits dry, rocky grassland in southern Europe and southwestern Asia.

EXPOSURE

Sources

Teucrin A is not available commercially. Alcoholic extracts of *Teucrium chamaedrys* are bitter, aromatic flavoring ingredients. As a dietary aid, germander was available as 200 mg or 270 mg capsules. Germander is also available as a tea combined with other herbs or alone. Germander herbal teas typically contain about 75–150 mg teucrin A/100 mL.

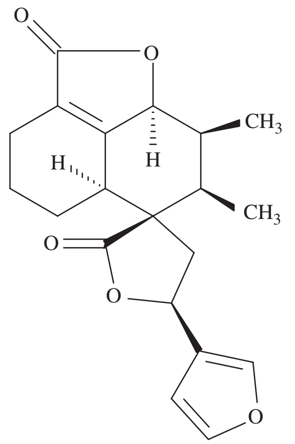

FIGURE 67.1. Chemical structure of teucrin A.

Medicinal Uses

Traditional

The use of *Teucrium polium* is a common herbal treatment for controlling diabetes mellitus.[6] In Qatar, a decoction of boiled leaves is a treatment for fever and stomach pain in children; crushed leaves are applied as compresses for wounds.[7] In Iran, *Teucrium polium* is a traditional medicine for the treatment of hypertension, hypercholesterolemia, inflammation, bacterial infections, seizures, pain, and diarrhea.[8] Other traditional uses of this herb include the treatment of anorexia, rhinitis, chronic bronchitis, gout, rheumatoid arthritis, fever, and dyspepsia. Animal studies indicate that anti-inflammatory activities of *T. polium* are low compared with other plant extracts.[9] The infusion of the leaves of *Teucrium* species also is considered a stimulant, antihelmintic, and a carminative (treatment of colic in infants).

Regulatory Status

Europe and the United States banned the use of germander as a dietary supplement because of the association between the use of germander as a diet aid and hepatotoxicity. Teucrin A is approved by the US Food and Drug Administration only as a flavoring agent in alcoholic beverages to add a bitter aromatic taste, primarily to drinks such as vermouth, flavored wines, bitters, and less commonly soft drinks. Alcoholic extracts of germander are permitted as flavoring agents.

PRINCIPAL INGREDIENTS

Chemical Composition

The aerial parts of *Teucrium* species contain a variety of constituents including glycosides, saponins, flavonoids, and several furan-containing neoclerodane diterpenoid compounds. Teucrin A (CAS RN: 12798-51-5) and several other neoclerodane diterpenoid compounds present in the aerial parts of *Teucrium* species probably contribute to the hepatotoxicity of these herbs.[10,11] Figure 67.1 displays the chemical structure of the C19-compound, teucrin A ($C_{19}H_{20}O_6$). Other diterpenoid compounds include teucrin G, teucrin H1, dihydroteugin, isoteuflidin, teuflin, teucvidin, teucrolivin A, teucrolivin B, and 6-β-hydroxyteuscordin.[12,13] The major constituents in ethanol extracts of *T. canadense* are phenylpropanoid glycosides, primarily verbascoside, whereas teucrioside is the predominant compound in ethanol extracts of *T. chamaedrys*.[5] These compounds help detect adulteration of skullcap (*Scutellaria lateriflora* L.) by *Teucrium* species because skullcap does not contain these phenylpropanoid compounds. Analysis of bitter alcoholic beverages from the Italian market demonstrated teucrin A concentrations ranging from non-detectable to 10 ppm as measured by high performance liquid chromatography (HPLC).[14] Essential oils from *Teucrium* species contain substantial amounts of monoterpene hydrocarbons (α-pinene, β-pinene, limonene, sabinene) and sesquiterpenes (elemol, germacrene D, T-cadinol, δ-cadinene, α-caryophyllene, isocaryophyllene, β-bisabolene).[15–17]

Physiochemical Properties

The molecular weight of teucrin A is 344 Da.

Mechanism of Toxicity

Although the exact mechanism by which germander causes hepatic necrosis is unclear, animal studies suggest that cytochrome CYP3A-mediated metabolism

produces electrophilic metabolites from furano neoclerodane diterpene compounds, such as teucrin A.[18] These electrophilic metabolites stimulate apoptosis by decreasing thiols (e.g., glutathione), increasing intracellular calcium, and activating Ca^{++}-dependent transglutaminase and endonucleases.[19] Animal studies indicate that the administration of teucrin A causes the same midzonal hepatic necrosis as powdered plant material from germander.[18] However, the exact role of teucrin A in producing germander-induced hepatotoxicity is undefined because germander contains a variety of furano neoclerodane diterpene compounds, and the amount (150 mg/kg) of teucrin A necessary to produce hepatoxicity in animal studies is much higher than the dose of germander in patients developing hepatotoxicity after ingesting germander. Consequently, hepatic injury may result from germander constituents other than teucrin A. In some case reports acute cholestatic hepatitis developed along with the transient appearance of serum autoantibodies (e.g., antimitochondrial M2, antimicrosomal epoxide hydrolase, antinuclear antibodies).[20,21] The presence of serum autoantibodies, eosinophilia, and eosinophilic infiltrates in liver samples from affected patients suggests the possibility of idiosyncratic reactions as well as indirect (i.e., through altered metabolism) hepatotoxic effects.[22]

DOSE RESPONSE

Medicinal Use

The recommended dose of germander (*T. chamaedrys*) for weight loss is 600–1600 mg daily, and case reports associate the use of germander in this dose range for 6 months with the development of jaundice and markedly elevated serum hepatic aminotransferases.[23,24] The Council of Europe established a NOAEL (no observed adverse effect level) of 0.4 mg/kg/day for teucrin A and a temporary tolerable daily intake of 0.12 mg/day based on a safety factor of 200.[25]

Toxicity

The dose and duration of germander required to produce hepatotoxicity is highly variable, and the appearance of liver toxicity is not clearly related to either the dose or the duration of use. The ingestion of germander tea up to 2 L daily for 6 months was associated with the development cholestatic hepatitis that resolved 1 month after stopping ingestion of the tea,[26] whereas two 10-day courses of germander tea were associated with the development of hepatic failure requiring liver transplantation.[27] A fatality resulting from massive hepatic necrosis and associated with the use of germander involved two courses of 450 mg daily for 2 weeks separated by 6 months.[28]

TOXICOKINETICS

The furano diterpenoid compounds in germander undergo metabolic activation to electrophilic metabolites capable of covalent binding to proteins in hepatocytes. The CYP3A isoenzymes catalyze the formation of reactive epoxides and/or unsaturated aldehydes from these aromatic compounds.[11]

CLINICAL RESPONSE

Occasional case reports temporally associate the herbal use of several *Teucrium* species with the development of hepatitis including *T. polium*,[27] *T. chamaedrys*,[23] and *T. capitatum*.[29] In some of these cases, readministration of germander was associated with the prompt recurrence of hepatitis.[23] These case reports involve both hepatocellular and cholestatic hepatitis, and the severity of the hepatotoxicity ranges from spontaneous recovery without sequelae to liver transplantation.[30] The clinical and histological changes associated with germander-induced hepatitis are nonspecific, and there are no unique features to distinguish this illness from viral or drug-induced hepatitis. Symptoms associated with germander-induced hepatitis include general malaise, anorexia, nausea, vomiting, painless jaundice, pruritus, dark urine, and light stools. Complete recovery typically occurs within 1–6 months after cessation of germander use.[23] A 37-year-old Greek woman was hospitalized 5 days after finishing the second 10-day course of *T. polium* tea following the development of jaundice, hypoprothrombinemia, and marked elevation of serum hepatic aminotransferases.[27] Histologic examination demonstrated massive centrilobular hepatic necrosis with portal tract fibrosis and bile duct proliferation. She developed severe liver failure (factor V = 12%) and she underwent successful liver transplantation. Rarely, germander use has been associated with fatal fulminant hepatitis.[28] Germander is one of a number of herbs that are associated with hepatotoxicity, including valerian, hops, skullcap, gentian, senna fruit extracts, mistletoe, chaparral leaf, and pyrrolizidine alkaloid-containing herbs.

DIAGNOSTIC TESTING

Neoclerodane diterpenoids in extracts of *Teucrium* species are detectable in concentrations of 0.24–0.90 μg/mL as measured by HPLC with UV-Vis detection at 220 nm.[12] The limits of detection and quantitation for teucrin A in alcoholic beverages were 0.1 ppm and

0.3 ppm, respectively, based on HPLC and liquid chromatography/electrospray ionization mass spectrometry.[14] Contamination of mad dog skullcap (*Scutellaria lateriflora* L.) by *Teucrium* species can be detected by analysis of ethanol extracts for phenylpropanoid compounds. This type of skullcap does not contain phenylpropanoid compounds, whereas the major phenylpropanoid compounds in ethanol extracts of *T. canadense* and *T. chamaedrys* are verbascoside and teucrioside, respectively.[5] The serum abnormalities associated with germander-induced hepatitis are nonspecific and include hyperbilirubinemia, elevated serum hepatic aminotransferases, and coagulation abnormalities (e.g., hypoprothrombinemia, factor V deficiency).

TREATMENT

Treatment of germander-associated hepatitis is supportive. The development of hepatic encephalopathy requiring liver transplantation may rarely occur. The role of *N*-acetylcysteine in replenishing depleted glutathione stores and limiting the progression of hepatic damage has not been investigated.

Chapter 68

GINGER
(*Zingiber officinale* Roscoe)

HISTORY

Ginger has been a part of traditional Chinese medicine at least since the 4th century BC, particularly for hepatic and other gastrointestinal disorders.[1] Two millennia before the birth of Christ, the Vedic literature of India included information on the use of ginger as a spice and an herb; Marco Polo also documented the use of ginger in India during the 13th century. The ancient Greeks and Romans used ginger as a spice. Traditional Arabian medicine used ginger for treating constipation, colds, bronchitis, cataracts, and stomach acidity.

BOTANICAL DESCRIPTION

Common Name: Ginger, Jiang [Chinese], Gingembre [French], Ingwer [German], Zenzero [Italian], Shoga [Japanese], Gengibre [Portuguese], Jengibre [Spanish]

Scientific Name: *Zingiber officinale* Roscoe

Botanical Family: Zingiberaceae (ginger family)

Physical Description: This slender, perennial herb has upright stems and narrow medium green leaves arranged in two ranks on each stem. Ginger reaches up to 1.5 m (~5 ft) in height with leaves about 2 cm (~0.8 in.) wide and 20 cm (~8 in.) long. This plant grows from a thick, aromatic underground stem (rhizome), which has a branched, uneven (warty) surface. The inflorescence forms a dense spike up to 8 cm (~3 in.) tall on a different stem than the leaves. The bracts are green with translucent margins and the small flowers are yellow-green with purple lips and cream-colored blotches. The fruiting body is a triangular-oval capsule containing many irregular, black seeds.

Distribution and Ecology: Ginger is indigenous to the warm, humid, shady tropical parts of southern Asia, but now this plant is cultivated commercially in Jamaica, West Indies, Haiti, China, and Nigeria. Harvest occurs about 5–6 months after planting fresh ginger and 8–9 months after planting dry ginger. Major producers of dry ginger include India, China, Taiwan, Sierra Leone, Nigeria, Jamaica, Fiji, and Australia.[2]

EXPOSURE

Sources

Ginger is a spice, flavoring agent, and herbal medicine used as both fresh and dried preparations of the ginger rhizomes. The rhizome is the plant part used for culinary as well as medicinal purposes. Some reduction in the major constituents (i.e., gingerols) occurs during the commercial drying process as a result of the dehydration of gingerols to shogaols.[3] The main source of ginger is the root and rhizome of *Zingiber officinale*. Ginger and ginger extracts are common constituents of foods and beverages including chutney, pickles, liquors, and bakery products. Common medicinal forms of ginger include fresh root, dried root, tablets, capsules (50–550 mg), liquid extract, tincture, and teas. Ginger oil is a steam distillate of fresh ginger rhizome or powdered ginger composed primarily of sesquiterpene

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

hydrocarbons (e.g., zingiberene).[2] Whole, intact rhizomes are the best source of the essential oil of ginger because of the presence of substantial amounts of the oil in the peel. Whole dried ginger has a loose corky layer; peeled ginger has a line of fiber bundles exposed by removal of the cork layer. Although there is no universal standard, ginger products are often standardized to gingerol content.

Medicinal Uses

Traditional

Traditional medicine in China, Japan, and India use the rhizomes and stems of ginger as a component of the herbal treatment of digestive disorders (indigestion, flatulence, constipation, nausea), headaches, rheumatism, colds, and cough. A large portion of traditional Chinese herbal remedies contain ginger. In the Ayurvedic medical practice in India, ginger is an herbal treatment for colds and other viral infections, poor appetite, digestive problems, arthritis, and headache.[4,5]

Current

Current medicinal uses of ginger include motion sickness, nausea and vomiting (postsurgical, pregnancy, chemotherapy-induced), and osteoarthritis. Ginger is one of the most common herbal treatments for nausea and vomiting in pregnancy along with chamomile, peppermint, and raspberry leaf. There is supportive evidence from a randomized controlled trial and an open-label study that ginger reduces the severity and duration of chemotherapy-induced nausea and vomiting.[6] The addition of ginger to a standard antiemetic regimen probably does not reduce the nausea or vomiting associated with chemotherapy.[7] Limited evidence supports the use of ginger for the reduction of nausea and vomiting associated with pregnancy, motion sickness, and surgery.[8] Most of the limited number of randomized clinical trials of ginger for the treatment of nausea and vomiting of early pregnancy demonstrate positive results, but these studies involve only several hundred patients and larger trials are necessary to determine the efficacy and safety of ginger relative to other treatments.[9] A randomized, controlled equivalence trial involving 291 pregnant women (<16 weeks gestation) administered daily doses of 1.05 g ginger capsules or 75 mg vitamin B6 did not detect a statistically significant difference between the two treatment groups as measured by the Rhodes index of nausea and vomiting scale.[10] There was no placebo group. No clinical trials of ginger for the treatment for hyperemesis gravidarum show consistent, long-term benefit.[11]

In a randomized, double-blinded trial involving 180 patients undergoing gynecologic laparoscopy, ginger did not reduce the incidence of postoperative nausea and vomiting after these procedures.[12] In a study of 28 volunteers, the administration of powdered ginger (whole root, 0.5 g or 1.0 g) or fresh ginger root (1 g) provided no protection against the motion sickness caused by a rotating chair.[13] Additionally, the administration of ginger did not significantly alter gastric function during motion sickness.

Regulatory Status

The German Commission E approves the use of ginger for dyspepsia, nausea and vomiting of pregnancy, and for prophylaxis of motion sickness. Ginger is listed on the General Sale List of the Medicines Control Agency of the United Kingdom. In the United States, ginger is a dietary supplement that is listed as generally recognized as safe (GRAS).

PRINCIPAL INGREDIENTS

Chemical Composition

The major pungent compounds in ginger are gingerols, particularly 6-gingerol. Other gingerols include 8-gingerol, 10-gingerol, methylgingerol, gingerdiol, dehydrogingerdione, gingerdiones, diarylheptanoids (curcuminoids), diterpene lactones, and galanolactone.[14] Gingerols are thermally unstable, and dehydrate (i.e., loss of hydroxyl group from C5 and a hydrogen from C4 with the formation of double bond between C4 and C5) to the corresponding shogaol compounds. Figure 68.1 displays the chemical structures of the major gingerol and shogaol compounds in ginger. Fresh ginger rarely contains zingerone and shogaols depending on the variety or cultivars, but the concentrations of these compounds increase significantly in dried preparations of ginger. Shogaol compounds also occur naturally in dried ginger along with vanillin, dihydroferulic acid, ferulic acid, and zingerone. Figure 68.2 displays the transformation of gingerols to zingerone, shogaols, and paradols.

In samples of fresh Australian ginger, 6-gingerol was the major pungent phenolic compound, while 8-gingerol and 10-gingerol were present in lower concentrations.[15] The mean concentration of these three gingerol compounds in fresh ginger rhizomes were $215 \pm 54\,\mu g/g$, $75 \pm 31\,\mu g/g$, and $73 \pm 26\,\mu g/g$, respectively. This study did not detect shogaol compounds in the ethanol extracts from fresh rhizomes, as measured by high performance liquid chromatography with UV detection (HPLC/UV). Analysis of fresh Hawaiian white and yellow ginger and

a methylene chloride extract of commercially processed dry ginger by HPLC detected 115 compounds.[16] In addition to gingerol and shogaol compounds, other constituents included paradols (5-deoxygingerols), isogingerols, isoshogaols, gingerdiones, methoxy-gingerols, mono- and di-acetoxy-gingerdiols, dihydro-paradols, diarylheptanoids, 4-vinylguaiacol, acetovanillone, and some methyl ether derivatives.

Ginger contains about 1–3.5% essential oil following steam distillation.[2] This product contains relative high concentrations of sesquiterpene hydrocarbons (e.g., zingiberene), relatively small amounts of monoterpene hydrocarbons, and oxygenated compounds compared with dry ginger. There are a variety of compounds (e.g., camphene, β-phellandrene, β-bisabolene, α-farnesene) in the essential oil depending on the extraction process, strain, and the source (dried, fresh). The main sesquiterpene hydrocarbons in ginger oil prepared from fresh ginger rhizomes were α-zingiberene (27–30%), α-curcumene (8–9%), β-sesquiphellandrene (4.8%), and bisabolene (3.2%) as measured by gas chromatography/mass spectrometry (GC/MS).[17] Minor constituents of the essential oil of ginger include acyclic α-farnesene and a variety of monoterpene compounds (limonene, myrcene, α-pinene, borneol, citronellol, geraniol, linalool).[14] Deterioration of ginger root may cause the formation of mycotoxins (e.g., mycophenolic acid) from the degradation of the root by fungi (e.g., *Penicillium brevicompactum*).[18] Currently, there is no evidence that the formation of mycophenolic acid in ginger causes human disease.

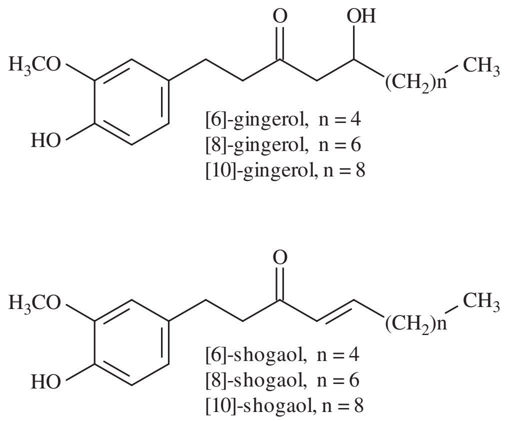

FIGURE 68.1. Chemical structures of major gingerol and shogaol compounds in ginger.

Physiochemical Properties

Gingerols exhibit novel reversible kinetics as a result of dehydration–hydration transformations with corresponding shogaols. The dehydration of gingerol is pH and temperature dependent with 6-gingerol being relatively stable at pH 4. The degradation of 6-gingerol is complete within 2 hours at pH 1 and 100 °C (212 °F).[19] 6-Gingerol is more pungent than other gingerol compounds (e.g., 8-gingerol, 10-gingerol). However, shogaol compounds are more pungent and lipophilic than corresponding gingerol compounds. *In vitro* studies suggest that gingerol inhibits thromboxane B_2 and prostaglandin D_2 formation by arachidonic acid.[20] However, the effect of *dried* ginger on thromboxane synthetase activity is dose-dependent, and up to 2 g dried ginger probably does not cause clinically significant platelet
